Abstract.

Cs_3C_{60} is a correlated superconductor under pressure, but an insulator under ambient conditions. The mechanism causing this insulating behavior is the combination of Mott localization and the dynamic Jahn-Teller effect. We show evidence from infrared spectroscopy for the dynamic Jahn-Teller distortion. The continuous change with temperature of the splitting of infrared lines is typical Jahn-Teller behavior, reflecting the change in population of solid-state conformers. We conclude that the electronic and magnetic solid-state properties of the insulating state are controlled by molecular phenomena. We estimate the time scale of the dynamic Jahn-Teller effect to be above 10^{-11} s and the energy difference between the conformers less than 20 cm^{-1} .

1. Introduction

Trivalent fulleride salts belong to the family of correlated superconductors, similar to high temperature superconducting cuprates [1, 2]. They show a dome-shaped T_c (superconducting transition temperature) versus lattice constant phase diagram [3] with an antiferromagnetic insulating state above a critical lattice constant [1]. The transition from metallic/superconducting to insulating behavior is generally attributed to Mott localization. Fullerides showing similar behavior have been known for a long time. Metallic fcc (face centered cubic) mixed alkali $\text{Cs}_x\text{A}_{(3-x)}\text{C}_{60}$ (A=K,Rb) phases have been prepared, which were in the lattice constant range where T_c decreases upon expansion [4]. Guest molecules, like cubane [5] or ammonia [6] were also used to expand the lattice. This approach leads in most cases to a change in crystal structure, inducing a crystal field with lower symmetry which distorts the fulleride molecular ions. Metal-insulator transitions in these compounds have been confirmed [7, 8], but since these occur in a low-symmetry crystal field, the external and internal contributions could not be unambiguously distinguished. Cs_3C_{60} is in this respect a key compound. It is an expanded structure, shows a metal-to-insulator transition upon application of pressure [3, 9] and retains its cubic structure in the whole pressure range.

Cs_3C_{60} has two cubic polymorphs, an ordered A15 [3] and a merohedrally disordered fcc one [10]. At ambient pressure they are insulators and magnetic with $S=1/2$, but turn into metals

upon application of pressure [11], exhibiting superconducting transition temperatures T_c up to 38 K [3]. The metal-insulator transition upon increasing distance between the fulleride ions and the localized magnetic moments point to strong electron-electron correlation and consequently, Mott localization.

The localization mechanism was suggested to involve a Jahn-Teller distortion [12], which is difficult to prove experimentally. Atomic displacements in the distorted molecular ions have been estimated to fall in the range of 0.05 ångstroms, hard to detect even by sensitive neutron scattering experiments. However, since the distortion involves a symmetry change, vibrational spectroscopy can be a sensitive indicator. The $T_{1u}(4)$ infrared-active mode at 1429 cm^{-1} is most widely used to detect both charge and symmetry changes in C_{60} [13]. From symmetry considerations for an I_h point group object placed in a cubic environment, it follows that this mode will not show splitting caused by the environment. Therefore, all splittings found can be directly related to the symmetry reduction following from the molecular Jahn-Teller effect.

2. The Jahn–Teller effect in solid fullerenes

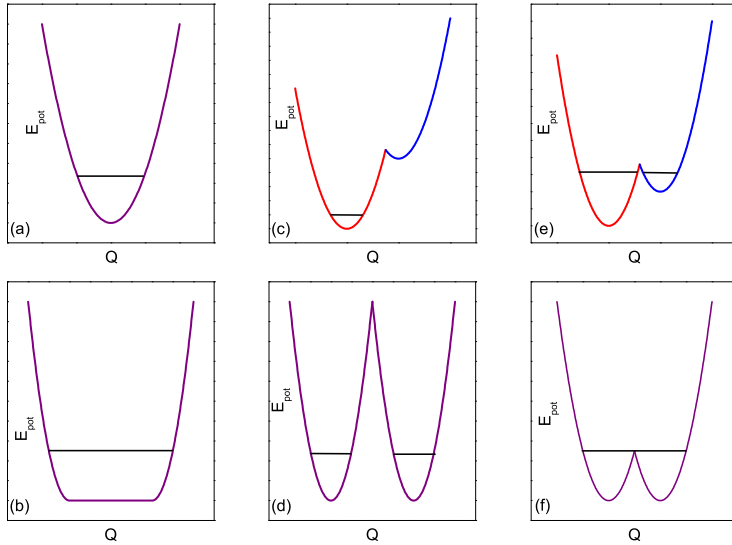

Figure 1. Possible potential energy surfaces of the C_{60}^{3-} molecular ion in Cs_3C_{60} . (a) The possible D_{2h} distortions in all directions have the same energy. (b) No energy barrier between differently directed distortions causes an average I_h symmetry. (c, e, f) Two inequivalent directions of differing energy separated by a small energy barrier. (c) Static distortion in one of the directions. (d) Two inequivalent directions of similar energy separated by a large energy barrier. A small energy difference between the two wells is possible. Static distortion. (e) Dynamic distortion with two solid-state conformers with differing population. (f) Hindered pseudorotation between differently directed distortions.

According to theoretical calculations [14] the symmetry of the Jahn–Teller distortion of C_{60}^{3-} is D_{2h} . The potential energy surface of a single distortion is schematically illustrated in Fig. 1 (a). The possible combinations of fifteen equivalent twofold axes among the symmetry elements of icosahedral C_{60} define thirty equivalent distortions among which the molecule can move. The corresponding motion is called pseudorotation (see the movie in the Supplementary Information). The molecule performing pseudorotation is dynamically distorted. If there is no barrier between the different D_{2h} distortions (free pseudorotation), the molecular symmetry will be restored to I_h in time average [15] (see Fig. 1 (b)). Introducing a barrier between the D_{2h} distortions results in hindered pseudorotation [15] (see Fig. 1 (e) and (f)). If the time scale of a spectroscopic

measurement is shorter than that of pseudorotation, the D_{2h} distortion can be detected. The time scale of infrared excitations being of the order of 10^{-11} s, spectra corresponding to distorted states correspond to pseudorotations slower than this value. The last possibility is that with a barrier high enough to cause static distortion along one special axis [15] (see Fig. 1 (c) and (d)).

In the solid one has to take into account the effect of the crystal field determined by the potential created by the neighboring Cs^+ ions. The undistorted site symmetry is T_h in these cubic crystals, so the crystal field alone would not lower the symmetry of the fulleride ions below that point group.[16]. The number of twofold axes along which Jahn-Teller distortion can occur is reduced to three, and if one considers the C_{60}^{3-} ion in a T_h point group there will be just two inequivalent directions. This is why two kinds of distortions appear in Fig. 1 (c)-(f).

Thermal expansion results in weaker crystal field acting towards equalizing the two kinds of distortions. In addition, at higher temperature the higher energy states become increasingly populated. Thus, for example, heating will lead from the state in Fig. 1 (c) to (e), and further to (f). Raising the temperature will also lower the barriers between potential energy wells (best seen in Fig. 1 (d)) and they can be more easily overcome.

3. Experimental

The Cs_3C_{60} samples used in this study were prepared by solution chemistry routes as described elsewhere [3, 10]. Sample composition and structure were determined by x-ray diffraction. Infrared measurements were done on both fcc-rich and A15-rich materials, in KBr pellets with 0.25 cm^{-1} resolution [16].

4. Signatures of the Mott insulating state

Figure 2. Infrared spectrum of A15 and fcc Cs_3C_{60} in the range of intramolecular vibrations at room temperature. The room temperature spectra of insulating C_{60} and metallic Rb_3C_{60} are included for comparison. The metallic character influences both the background and the lineshape.

The measured infrared spectra of both polymorphs together with that of C_{60} and of metallic Rb_3C_{60} are shown in Fig. 2. The spectrum of pure C_{60} consists of four lines, a consequence of the high symmetry of the fullerene ball [17]. In accordance with previous data [18], the highest frequency mode softens due to the charge added on the fullerene, showing approximately the same shift in Cs_3C_{60} and in Rb_3C_{60} . The lineshape of this mode, however, is different for Rb_3C_{60} and for Cs_3C_{60} . Rb_3C_{60} has a Fano lineshape [19] as a consequence of coupling between vibrational states and the electronic continuum of the same energy. The non-Fano lineshape in both polymorphs of Cs_3C_{60} signals the absence of metallic electrons, therefore these materials are insulators, in agreement with previous measurements [1]. Metallic electrons also cause a

continuous background absorption, which is indeed present in Rb_3C_{60} , but not in either of the two Cs_3C_{60} polymorphs.

Another signature of the insulating state is that it facilitates the appearance of the Jahn–Teller effect: molecular ions can suffer a Jahn–Teller distortion only if their electrons are localized. The asymmetrically broadened lineshape in both Cs_3C_{60} compounds (Fig. 2) indicates splitting of the vibrational lines, a consequence of the symmetry reduction owing to the Jahn–Teller distortion [16]. To further study the temperature and the polymorph dependence of the splitting, temperature dependent measurement were performed on both Cs_3C_{60} polymorphs.

5. Jahn–Teller effect in Cs_3C_{60}

Figure 3. Temperature-dependent IR spectra of A15 Cs_3C_{60} (left: full spectrum, right: range of $T_{1u}(4)$ and $G_u(6)$ modes). The splitting changes gradually.

Figures 3 and 4 illustrate the gradual changes in the splitting, characteristic of both polymorphs (although not exactly identical). Newly activated low intensity modes between 600–800 cm^{-1} can also be observed at low temperature. These changes indicate that the symmetry lowering is different in the two Cs_3C_{60} polymorphs. The weak new modes disappear at differing temperatures underlining the smooth nature of the transition. As we will see, this is a sign of temperature-dependent solid-state conformers, implying a dynamical Jahn–Teller effect [15].

The low-temperature multiple peak structure and its dependence on crystal structure is a result of the interplay between crystal field and Jahn–Teller distortion. The Cs^+ ions that surround the C_{60}^{3-} ion constitute a cubic environment and do not cause splitting in the T_{1u} modes. However, the energies of molecular distortions, that are equivalent in a free molecular ion, can differ slightly in a crystal when pointed at different crystallographic directions. The observation of the signatures of the Jahn–Teller distortion in the vibrational spectra rules out the case of Fig. 1 (b) (free pseudorotation). Statically ordered distortions in the lattice with the same energy (Fig. 1 (a)) would lead to a temperature-independent spectrum consisting of one set of lines (maximum 3+4, for triply degenerate T_{1u} and quadruply degenerate G_u , respectively) and is also contrary to observation. The number of possible allowed IR lines (in principle 1^* or $2^*(3+4)$) corresponds to the number of populated potential energy wells (1 in Fig. 1 (a-c) and 2 in Fig. 1 (d-f)). According to the experiments, this number continuously decreases on heating. This finding can be qualitatively explained by a model where the population of the wells changes with temperature.

Figure 4. Temperature dependent IR spectra of fcc Cs_3C_{60} . The splitting changes gradually.

The simplest of these models is that of the static-to-dynamic transition (from Fig. 1 (d) to (f)) on heating. At low temperature the differently directed distortions would be frozen in with static and disordered distortion. Thermal expansion lowers the barrier and the increased thermal energy from pseudorotation helps to overcome it. In this case the transition would be located in a considerably narrower temperature range, but we observe a continuous change over the whole temperature range we measured. The model based on Fig. 1 (d), where the barrier is too high for a transition even at high temperature, can also be rejected based on the measured temperature-dependent infrared data. A transition could also happen from the static distortion shown in Fig. 1 (c) to the dynamic ones Fig. 1 (e) and (f). The number of lines should first increase on heating, then start to decrease. As we cannot prove such a behaviour, this case can also be ruled out.

This leaves us with the dynamic distortions Fig. 1 (e) and (f), the latter developing from the former on increasing temperature. This situation corresponds to different solid-state conformers with different occupational probability [16]. On heating, both their energy difference and their populational difference gradually disappears [15], as observed in the spectra. Fewer kinds of distortions mean fewer lines in the infrared spectra. The two equilibrium conformations with a low barrier (Fig. 1e) are connected by hindered pseudorotation [15]. The fact that we observe the distorted states puts the lower limit of the time scale of this pseudorotation to 10^{-11} s, and the lowest temperature being 28 K can be reconciled with an upper limit of 20 cm^{-1} for the barrier between the two conformers.

6. Conclusions

We studied the temperature-dependent infrared spectra of both polymorphs of the correlated superconductor Cs_3C_{60} in their normal state. The vibrational signatures reveal the insulating state of these materials, and establish the interplay of Mott localization and the Jahn-Teller effect in forming this state. In addition, the crystal field influences the vibrational levels making the spectra temperature- and polymorph-dependent. The presence of temperature-dependent solid-state conformers validates the proof of the dynamic Jahn-Teller effect.
