37 **Summary**

38 Mast seeding is a crucial population process in many tree species, but its spatio-temporal

39 patterns and drivers at the continental scale are still unknown. We show for a large dataset

40 (almost 8,000 masting observations across Europe for the period 1950-2014) the spatial

41 pattern of masting across the entire geographical range of European beech, how it is

42 influenced by precipitation, temperature, and drought, and the temporal and spatial stability

43 of masting-weather correlations. We used Mantel tests and hierarchical clustering to analyze

44 spatial patterns. Beech masting exhibited a general distance-dependent synchronicity and a

45 pattern structured in three broad geographical groups consistent with continental climate

46 regimes. Spearman's correlations and logistic regression evidenced a general pattern of beech

47 masting correlating negatively with temperature in the summer two years prior to masting,

48 and positively with summer temperature one year before masting (i.e., 2T model). The

49 temperature difference between the two previous summers (DeltaT model) was also a good

50 predictor. Moving correlation analysis applied to the longest eight chronologies (74 to 114

51 years) revealed stable correlations between temperature and masting, confirming consistency

52 in weather cues across space and time. These results lends robustness to the attempts to

53 reconstruct and predict mast years using temperature data.

Introduction

60 **Introduction**

61

62 Mast seeding (or masting) is the synchronous and highly variable production of fruits and

63 seeds (Pearse *et al.*, 2016), and is a crucial population process in many grass, shrub and tree

64 species (Kelly & Sork, 2002). As a form of information-mediated interaction, masting

65 synchrony has important implications for broader ecological patterns emerging at the

66 community and ecosystem levels (Mescher & Pearse, 2016). The synchrony of masting

67 varies across species (Norden *et al.*, 2013), time (Drobyshev *et al.*, 2010), and space (Suzuki

68 *et al.*, 2005), with cascading effects on plant regeneration (Ascoli *et al.*, 2015), community

69 composition (Lichti *et al.*, 2014), nutrient fluxes (Zackrisson *et al.*, 1999), carbon allocation

70 (Müller-Haubold *et al.*, 2013), and trophic cascades (Blackwell *et al.*, 2001), including those

71 that involve organisms that carry human infectious diseases (e.g., Hantaviruses: Clement *et*

72 *al.*, 2010; Lyme disease: Ostfeld & Keesing, 2000).

73

74 Describing and predicting masting is therefore critical to better understand population

75 dynamics, assess present and future ecosystem resilience, and design adaptive forest

76 management strategies (Wagner *et al.*, 2010). In recent decades, the temporal pattern of

77 masting has been described for several species in boreal, temperate, and tropical biomes

78 (Koenig & Knops, 2000). A growing body of research has elucidated some of the

79 environmental and physiological cues of masting (e.g., Kelly, 1994; Kelly & Sork, 2002;

80 Kelly *et al.*, 2013; Miyazaki *et al.*, 2014; Pearse *et al.*, 2016), and suggested several

81 mechanisms responsible for the synchronization of masting in individual species from the

82 stand to the regional scale (Satake & Iwasa, 2000; Koenig & Knops, 2013; Koenig *et al.*,

83 2015).

84

85 The oldest and simplest hypothesis for masting states that seed crops vary in response to

86 weather variation (Büsgen *et al.*, 1929; Kelly, 1994). In particular, temperature and

87 precipitation in the years previous to seed production have been consistently related to

88 masting (e.g., in grasses: Schauber *et al.*, 2002; shrubs: Mayer & Pendleton, 2015; trees: Bisi

89 *et al.*, 2016). The nature of such relationships can be either correlative, i.e., weather is a "cue"

90 that triggers other processes and that plants are able to sense (e.g., Kelly & Sork, 2002; Kelly

91 *et al.*, 2013), or causal, in the case that weather directly influences resources and other

92 proximate causes of masting (Monks *et al.*, 2016; Pearse *et al.*, 2016). In the absence of

93 manipulative experiments, we cautiously consider weather variables as cues. However, few

3

94   studies have tested whether such cues are constant in space and time across an entire species'
95   distribution range (e.g., Masaki *et al.*, 2008). In other words, do spatial and temporal
96   variations in masting emerge from (a) variations in weather, or (b) differences in local plant
97   response to the same weather patterns, e.g. as a consequence of inter-population differences
98   and adaptations in genes that regulate flowering (Tan and Swain, 2006)? Addressing this
99   question will provide important information on predicting masting both in the short and at the
100   long term, such as in the case of masting responses to climate change and the consequences
101   on large-scale ecosystem processes.
102
103   The aims of this paper are to: i) describe the spatial pattern of masting across the entire
104   distribution of European beech (*Fagus sylvatica* L.), one of the most important European
105   forest species (Fig. 1a); ii) measure the strength of the relationship between beech masting
106   and selected weather variables referring to precipitation, temperature, and drought; iii) assess
107   the stability of masting-weather correlations through space (i.e., whether the strength, timing,
108   and relative importance of weather cues vary across geographical space) and time.
109

110   **Materials and methods**
111
112   *Beech masting data*
113
114   To address such questions, we used a recently available, long-term, large-scale database of
115   masting for European tree species (MASTREE: Ascoli *et al.*, 2017). Each observation was
116   characterized by the following measurements: the date of inclusion in the database, the
117   masting proxy considered (e.g., seed, pollen), the scale of measurement of the original data
118   (continuous or ordinal), the year of measurement, the NUTS-1 (Nomenclature of Territorial
119   Units for Statistics version 2013, level 1, i.e., European administrative subdivisions
120   corresponding to macro-regional aggregations) [data source: GISCO – Eurostat (European
121   Commission)] where the observation was recorded (Fig. 1b), the start and end year of the
122   series, and the length of the continuous recording series to which each observation belongs
123   (range: 1-191 years). Non-EU countries where beech masting data were recorded (i.e.,
124   Ukraine, Serbia, Switzerland, Bosnia and Herzegovina) were also included in the database
125   with dummy NUTS-1 codes. Observations where the country was known but the precise
126   geographical location was uncertain were assigned a NUTS-0 attribution (i.e., country level).
127

4

128   All database records belonging to series with length ≥5 years were associated to a 5-class

129   ordinal measurement (ORDmast) from (1) very poor masting to (5) very abundant masting

130   (Ascoli et al., 2017). To build our target variable we extracted values of ORDmast for beech

131   in the period 1950-2014 (for spatial pattern analysis and Spearman's correlations) or 1901-

132   2014 (for ordinal regression and moving correlation analysis), because antecedent

133   observations were sparse and unevenly spread across the continent. Pollen and flowering data

134   were excluded, as pooling different masting proxies may introduce some noise, such as

135   would happen should flowers' crops not mature into fruits owing to environmental

136   constraints. A total of 769 individual series covering 7983 annually resolved observations

137   from 22 European countries was selected for further analyses.

138

139   *Data treatment*

140

141   To obtain long masting series with a minimum amount of missing data, individual masting

142   series were aggregated into 61 NUTS-1 chronologies (NC) by using the most frequently

143   observed masting class for each year (Table S1). The highest masting class was used in case

144   of multi-modality, but the impact of a different choice would be negligible (mean

145   Spearmans's correlation between NC calculated using highest and lowest masting class in

146   case of multi-modality = 0.91, range = 0.68 to 1.00). All forests within a NUTS-1 should

147   have homogenous climatic and ecological characteristics; the assumption was tested by

148   computing the mean Spearman's correlation coefficient between individual weather series

149   (see "Weather cues analysis", period 1901-2014) and between individual masting series in

150   each NUTS-1 (henceforth "intra-NUTS correlations") with ≥ 7 years of observation in

151   common. This sample size was chosen as a trade-off between the need for robustness (critical

152   value for Spearman's correlation with n=7 and p =0.05: rho = 0.79) and data inclusion (i.e.,

153   keeping at least 60% of all NUTS-1 into the analysis). Possible inflation of cross-correlation

154   values due to temporally autocorrelated series was corrected by calculating adjusted degrees

155   of freedom according to Dutilleuil *et al.* (1993). Correlation coefficients computed on <30

156   observation pairs were corrected according to Hotelling's (1953) second-order

157   transformation. Intra-NUTS weather correlations were always higher than 0.9, except for

158   precipitation (higher than 0.6). Of 36 NUTS-1 with at least two masting series sharing ≥7

159   elements, 30 had a significantly positive intra-NUTS correlation, with an average value of

160   0.66 (Fig. S1; Table S2).

161

5

162 The analyses were carried out according to the following scheme: we used Mantel (1967)

163 tests and hierarchical clustering to analyze spatial patterns, Spearman's correlations and

164 ordinal logistic regression to measure the relationship between masting and weather, and

165 moving correlation analysis to assess the temporal stability of such relationship.

166

167 *Spatial analysis of masting patterns*

168

169 To address our first objective, we analyzed the spatial structure of masting synchrony at the

170 continental scale by running a Mantel test (2000 permutations) on NC. This test measures the

171 correlation between two dissimilarity matrices containing measures of geographical and

172 ecological distance. Here, it addresses the hypothesis that masting chronologies farther apart

173 would be less similar to one another (de-synchronized) than closer ones.

174

175 Time series of seed production may exhibit lagged negative temporal autocorrelation (e.g.,

176 Koenig & Knops, 2000) and non-stationarity (i.e., temporal trends; Allen *et al.*, 2014). Both

177 may alter cross-correlation analyses. Therefore, all NC were checked for temporal

178 autocorrelation (max order =1, excluding segments with <7 consecutive years of observation

179 which may bias the autocorrelation function; Sork *et al.*, 1993) by fitting a Cumulative Link

180 regression Model (CLM: Agresti, 2002) (probit link with 2000 iterations) against NC of the

181 previous year (NC_{-1}). Of 47 NUTS-1 chronologies with ≥ 7 consecutive years of observation,

182 21 had a significantly negative autocorrelation at lag 1 (Table S2). NC that exhibited

183 significant temporal trends (i.e., slope of linear regression against year of observation

184 significant at $p \leq 0.05$) were detrended by extracting regression residuals (negative trend: ITI,

185 SI0; positive trend: DEA, DEB, DEC, PL1, PL2, PL5, PL6).

186

187 We used coordinates of NUTS-1 centers to compute the geographical distance matrix for the

188 Mantel test, and the index of Suzuki *et al.* (2005), a metric derived from Spearman's

189 correlation coefficient, for the masting dissimilarity matrix. Only NC pairs with an overlap of

190 ≥ 7 consecutive years of observation were included in the latter. Furthermore, we ran two

191 unidirectional Mantel tests as a function of distance along longitude (Dlon) and latitude

192 (Dlat) only, by fixing the other coordinate to its mean value across all NUTS-1, to scrutinize

193 the structure of masting along the two orthogonal geographical directions. Mantel tests were

194 run with package *ncf* version 1.1 (Bjornstad, 2015) for the R statistical framework (R Core

195 Team, 2016).

6

196

197 Secondly, we assessed the geographic pattern of beech masting in Europe by running a

198 hierarchical cluster analysis on NC using Ward's minimum variance method (Murtagh &

199 Legendre, 2014), which minimizes within-cluster distances relative to between-cluster

200 distances (Ward, 1963). Only NC pairs sharing ≥7 consecutive years of observation were

201 included in the dissimilarity matrix. NUTS-1 not satisfying such condition when paired

202 against every other NUTS-1 were filtered out. Dissimilarities between individual NC pairs

203 with an insufficient number of observations (4.9% of all NC pairs) were simulated by a linear

204 model of the form $a_0 + a_1$ Dlon $+ a_2$ Dlat ($a_0 = 18.41$, $a_1 = 1.61$ x10^{-5}, $a_2 = 1.54$ x10^{-5}, adjusted

205 $R^2 = 0.35$; F-statistic $= 709.9$ on 2 and 2672 degrees of freedom, p-value < 0.001). We

206 determined the optimal number of clusters by maximizing the index by Dunn (1974) with the

207 R package *NbClust* (Charrad *et al.*, 2014), and computed cluster stability by nonparametric

208 bootstrap with the R package *fpc* (Hennig, 2015). The validity of each cluster was also

209 assessed by checking that the mean Spearman correlation between all NC pairs in each

210 cluster was higher than the mean correlation between all pairs from two different clusters.

211

212 *Weather cues analysis*

213

214 To measure the strength of weather cues of masting, we calculated Spearman's correlations

215 between each NC (filtered on ≥ 7 years of observation, after detrending if needed: see above)

216 and the following variables: Mean monthly temperature (MEAN), monthly mean of daily

217 maximum temperature (MAX), monthly mean of daily minimum temperature (MIN),

218 monthly precipitation (PRE), three-months Standardized Precipitation Index (SPI3; McKee *et*

219 *al.*, 1993), and three-months Standardized Precipitation and Evaporation Index (SPEI3;

220 Vicente-Serrano *et al.*, 2010). Weather series were obtained by averaging monthly data

221 across all cells included in each NUTS-1 from the gridded database CRU TS 3.23 (0.5°

222 resolution; years 1901-2014) (Harris *et al.*, 2014), and detrended before all subsequent

223 analysis by running a linear filter on each individual monthly variable for the timespan

224 selected (1901-2014 or 1950-2014). SPI3 was calculated using the nonparametric approach

225 described by Hao *et al.* (2014), in which the probability distributions are calculated

226 empirically (Gringorten, 1963), rather than by fitting a parametric distribution function.

227 SPEI3 was calculated from the difference between available water (i.e., three-month sum of

228 PRE) and the potential evapotranspiration, which is based on the FAO-56 Penman–Monteith

229 estimation (Allen *et al.*, 1998) and directly gridded by the CRU. The difference was fit to a

7

230 log-logistic probability distribution to transform the original values to standardized units

231 (Vicente-Serrano *et al.*, 2010). SPEI3 measures the climatic water balance and therefore

232 provides a more reliable and spatially comparable measure of drought severity than

233 precipitation alone (Vicente-Serrano *et al.*, 2013). Data extraction and calculation of drought

234 indices were performed with the R packages *cruts* (Taylor and Parida, 2016) and *SPEI*

235 (Begueria and Vicente-Serrano, 2013). Correlations (years 1950-2014) were computed for all

236 36 months of a three-year period, including the calendar year of seed production and the two

237 years prior (lag -1 and -2). After preliminary scrutiny of the most significant correlations, we

238 also ran correlations against aggregated summer (June-July) weather variables of one and two

239 years prior to masting, and against the difference (Delta) between values of each weather

240 variables measured one and two years prior (e.g., Delta Temperature, Kelly et al. 2013). The

241 absence of non-linear relationships was visually checked before running all correlations. For

242 each correlation, significance was tested at the 95% confidence level, with a simple

243 Bonferroni correction, i.e. adjusting the required alpha value according to the number of

244 comparisons (0.05/36), to account for multiple comparisons. Finally, to assess the role of

245 weather in determining the spatial pattern of masting in Europe, we ran a hierarchical cluster

246 analysis of all six weather variables for the period 1950-2014, using Suzuki's dissimilarity

247 index and three optimal clusters, and compared them against masting clusters by computing

248 the overall proportion of matches between masting and weather clusters.

249

250 *Spatio-temporal stability of weather cues*

251

252 To test for spatial stability of masting-weather relationships, we fitted a linear model of

253 Spearman's correlation coefficient between masting and MAX of June, July, and August of

254 the one and two years prior, and latitude. Subsequently, we modeled the eight longest NC

255 (DE1, DE2, DE9, DEF, DK0, NL1, SE2, UKJ – including 74 to 115 yearly observations in

256 the period 1901-2014) as a function of detrended weather variables, using ordinal logistic

257 regression within the R package *rms* (Harrell, 2016). In this analysis, NC_{-1} was used as an

258 additional independent variable, to account for potential temporal autocorrelation resulting

259 e.g. from resource depletion (Davis, 1957) or resource switching (Kelly & Sork, 2002). All

260 models were fitted with 44-65 observations (years 1950-2014), and validated using both a

261 new prediction interval (years 1901-1949, 30-41 observations for each NC except NL1 with

262 10), and a bootstrapped leave-one-out cross-validation run on the calibration time period.

263 Weather variables (i.e., MAX and PRE in June and July -1 and -2, hereafter MAX_{JUN-1},

8

264   MAX_{JUL-1}, MAX_{JUN-2}, MAX_{JUL-2}, PRE_{JUN-1}, PRE_{JUL-1}, PRE_{JUN-2}, PRE_{JUL-2}) were selected

265   based on the previous correlation analysis and evidence from literature on beech masting

266   (e.g., Piovesan and Adams, 2001; Drobyshev *et al.*, 2010). The absence of non-linear

267   univariate relationships was visually checked before running the models. All independent

268   variables were z-transformed to ensure comparability of effect sizes within models; to

269   account for collinearity among weather variables, optimal models were selected using

270   backward stepwise selection based on the Akaike Information Criterion (AIC). Nagelkerke

271   R^2 was used to compare models for different NC.

272

273   To test for temporal stability of masting-weather relationships, each of the 8 long NC was

274   fitted against the four most important weather variables selected by logistic models and

275   correlation analysis (i.e., MAX_{JUN-1}, MAX_{JUL-1}, MAX_{JUN-2} and MAX_{JUL-2}), using year as an

276   interaction factor. If the year x MAX interaction is significant, that will suggest a temporal

277   change in masting sensitivity to maximum summer temperatures. Moreover, to test also for

278   non-linear trends in correlation values, we additionally ran a moving correlation analysis

279   (MCA) between MAX_{JUN-1}, MAX_{JUL-1}, MAX_{JUN-2} and MAX_{JUL-2}, and the same 8 NC. MCA

280   was conducted on detrended weather variables using Spearman's rank correlation and a

281   window size of 28 years, i.e., the largest window giving 4 independent intervals for the

282   period 1901-2014. Most series had some missing values, but a minimum of 15 values (i.e.,

283   >50% of years observed) was required for any window.

284

285   The R code used for analyses is provided in Supplementary Information Script S1.

286

287   **Results**

288

289   Graphical analysis of mapped NUTS-1 chronologies (Fig. S2) suggested a certain degree of

290   spatial structuring, except when most of the continent exhibited high seed production (e.g. in

291   1995). The existence of spatial aggregation in masting was confirmed by significantly

292   positive (p <0.01) Mantel correlation coefficients (M =0.53, 0.31, and 0.42 for the isotropic,

293   latitude-only, and longitude-only tests, respectively) (Fig. 2, Fig. S3). Hierarchical clustering

294   of NC produced three relatively stable clusters broadly corresponding to southern (SO,

295   cluster stability =56%), northern (NO, 68%), and eastern Europe (EA, 71%) (Fig. 3; Fig. S4).

296   Further dendrogram subdivisions suggested differences between Romania, Poland, and all

9

297   other NUTS-1 in EA, between Mediterranean (central Italy) and all other NUTS-1 in SO, and

298   between Atlantic (France, United Kingdom) and central NUTS-1 in NO.

299

300   Correlation analysis revealed consistently positive correlations between NC and previous

301   summers' temperature at the NUTS-1 level across the species distribution (and in all three

302   clusters), especially when using seasonal summer weather or two-year differences (Fig. 4).

303   Correlations were generally strongest for MAX and MEAN (Fig. S5), and to a lesser degree

304   MIN (Fig. S6) (mean correlation across all NUTS-1: 0.38, 0.36, 0.39, -0.21, and 0.28, 0.24,

305   0.28, -0.13, respectively against MAX, MIN, MEAN, and PRE in June-July of two years

306   prior and one year prior). MAX_{AUG-1} was not a consistent signal across Europe. One third of

307   NUTS-1 did not have significant correlations ($R \geq 0.35$ with a sample size of n=61) either

308   with MAX_{JUN-1}, MAX_{JUL-1} or MAX_{AUG-1}, especially those in the Netherlands, Italy, and the

309   Carpathian region (the latter were based on shorter records). Temperature in the summer two

310   years prior to masting was negatively correlated with NC across the species distribution (Fig.

311   4), and particularly in cluster NO. Consequently, DeltaT usually produced significant

312   correlations against masting. Weaker (and rarely significant) correlations were found for the

313   autumn and early winter two years prior to masting (negative MAX_{NOV-2} in Austria, Czech

314   Republic, Poland and Germany, positive MAX_{DEC-2} in Mediterranean France) and for the late

315   winter and spring of the year before masting (negative MAX_{FEB-1} in Belgium and United

316   Kingdom, positive MAX_{MAR-1} in Austria, Poland, and Croatia, negative $MEAN_{APR-1}$ in Italy

317   and France). No consistent pattern of correlations was found between NC and temperature in

318   the year of masting, although some regional patterns during spring were found (e.g. positive

319   correlations with MAX_{FEB} in Poland and United Kingdom, or with MAX_{MAY} in Poland).

320

321   Correlations between NC and PRE were weaker and much less consistent than with

322   temperature (Fig. S7). Significantly positive correlations with PRE in two summers prior and

323   negative in one summer prior emerged locally (e.g., in Germany, UK, France, and

324   Switzerland), although a clear distinction between clusters was not evident. Correlations with

325   $summer_{-2}$ were on average stronger than with $summer_{-1}$. SPI3 and SPEI3 were similar to

326   MAX, with strong and significant correlations in $summer_{-2}$ and, less strongly, $summer_{-1}$ (Fig.

327   S8; Fig. S9), albeit on a more restricted geographic extent (Germany, Denmark, United

328   Kingdom, Belgium, Sweden). Spring water balance (PRE, SPEI3) was generally uncorrelated

329   to masting in beech (except a positive correlation of PRE_{APR-1} in France and PRE_{APR0} in

330   Croatia).

10

331

332   Overall, most NC conformed to a general pattern of negative correlations with temperature in

333   the summer two years prior to masting, and positive correlations with temperature in the

334   summer one year prior to masting (Table 1), with no substantial differences in the response of

335   masting to weather among geographical clusters. Precipitation and drought indices were less

336   strongly and consistently correlated with NC than temperature. Additionally, neither

337   temperature nor precipitation in the year of masting was consistently correlated with NC,

338   except for a positive influence of early spring temperature in northern Europe. The

339   geographical pattern of weather variables in the period 1950-2014 was very similar to that of

340   masting, with rates of agreement between masting and weather clusters ranging from 62%

341   (TMN) to 87% (PRE) (Table 3).

342

343   Latitude was not a significant driver of the correlation between masting and MAX (Fig. S10).

344   Ordinal logistic models fitted to the eight longest NC had medium to high explanatory power

345   (range of Nagelkerke R^2: 0.33– 0.72, mean = 0.57). Stepwise AIC selection isolated between

346   three and six independent variables (Fig. 5), which corroborated the results of weather

347   correlations computed for NUTS-1. The most commonly selected terms were MAX_{JUL-1}

348   (selected in all models) and MAX_{JUL-2} (all but one). MAX_{JUN-1} or MAX_{JUN-2} were

349   additionally selected in five and six models, respectively. NC_{-1}, with a negative coefficient,

350   was selected in five models. Precipitation terms were selected less frequently than

351   temperature, and only half of the models included any precipitation term. Standardized

352   coefficients for precipitation were generally lower than those for temperature, indicating a

353   smaller effect on masting. Model validation produced a mean Nagelkerke R^2 of 0.46 after

354   bootstrapped leave-one-out cross-validation (range = 0.53-0.65), and 0.40 after extrapolation

355   to 1901-1950 (0.21-0.55), indicating that models were partially able to reproduce masting

356   variation outside of the training dataset (Table 2). Clusters SO and EA were represented by

357   only one model each, with the latter showing a lower explanatory power and weaker summer-

358    $_1$ effects.

359

360   Temporal trends in masting were significant in NL1, DE1 (negative trend), DE2, and DE9

361   (positive); however, the interaction between time and summer MAX was significant only in 3

362   out of 32 cases (Table 2). MCA applied to the longest eight chronologies revealed generally

363   stable correlations between temperature and masting, particularly for MAX_{JUL-1} and MAX_{JUL-}

364    $_2$ (Fig. 6, Fig. S11), except for DK0 and DE9 (increasingly stronger correlation through time).

11

365   Most NC showed decade-long periods when correlations with MAX were non-significant,

366   although the timing of these periods was not synchronized across Europe. Some NC showed

367   evidence of "switching" between July and June temperature (i.e., periods of reduced

368   correlations with MAX_{JUL} corresponded to increased correlations with MAX_{JUN}, e.g. DK0),

369   but in others the temporal variations in the strength of all four correlations were homogenous

370   (e.g., UKJ). Some NUTS-1 showed "parallel" correlation trends with year-1 and year-2, i.e.,

371   a decreasing importance of positive MAX_{-1} corresponding to an increasing importance of

372   negative MAX_{-2}, especially in DE1 and DE2; however, the dataset is too sparse to strongly

373   generalize such evidence.

374

375   **Discussion**

376

377   Using a distribution-wide dataset with around 8,000 individual observations, we have shown

378   that a strong spatial structure exists in masting patterns of *F. sylvatica* across its distribution

379   range. Synchrony was higher between neighboring populations (Fig. S1), particularly in

380   northern Europe, and strongly declined with distance (Fig. 2), consistent with previous

381   findings for other temperate species (Koenig & Knops, 2000; Garrison *et al.*, 2008; Gallego

382   Zamorano *et al.*, 2016). While synchrony generally declined with distance (e.g., "typical"

383   years with partial masting at the continental scale such as 2002 or 2009; Fig. S2), continental-

384   scale mast years occurred on several occasions, e.g. twice in the last 40 years (1976 and

385   1995, with less comprehensive but still widespread events in 1992, 2006 and 2011; Fig. S2).

386   This is consistent with what has been previously reported for beech at both continental

387   (Nussbaumer *et al.*, 2016) and regional scale (e.g., Hilton & Packham, 2003), and it is based

388   on an unprecedented sample size. These distribution-wide mast events may have important

389   implications for large-scale, long-distance ecological processes, such as forest regeneration

390   after large disturbances (Peters *et al.*, 2005; Ascoli *et al.*, 2015; Funk *et al.*, 2015), pollen-

391   and seed-related gene flow (Kremer et al. 2012), bird migration (Koenig & Knops, 2001),

392   predator-prey population dynamics (Blackwell *et al.*, 2001), pest and disease diffusion

393   (Liebhold *et al.*, 2000), biological invasions (Harper, 2005), forest species range shift

394   (Takenaka, 2005), and climate resilience (Mustin, 2013). Even if masting synchrony had little

395   impact over and above the local effects through predator satiation and/or enhanced

396   pollination, and is simply a result of the weather cues used locally, when the latter co-vary

397   across large areas the ecosystem consequences may be far-reaching.

398

12

399   Furthermore, the temporal variability of masting in beech showed a distinct spatial structure

400   during the last 65 years, with three clusters located in northern, southern and eastern Europe

401   (Fig. 3). These clusters correspond closely to weather patterns (Fig. S13), and broadly to

402   regions of Europe influenced by different climate regimes: the northern cluster corresponds

403   to the region of western Europe associated with an oceanic climate strongly influenced by the

404   Atlantic (Cfb according to Peel *et al.*, 2007), the southern cluster overlaps with the

405   Mediterranean region (Csa), while the eastern cluster is the most continental one and is less

406   influenced by Atlantic weather (roughly corresponding to Dfb). Indeed, the longitude-based

407   Mantel-test showed a lower correlation coefficient than the latitude-based test, which may be

408   a consequence of weather events characterized by a longitude-based spatial pattern prompting

409   synchronized masting (Fernández-Martínez *et al.*, 2016a). Similar spatial structuring in beech

410   has been found by local masting studies, which explained it by an increasing influence of

411   spring frost in more continental areas (Gross, 1934), but also by tree-ring studies, which

412   linked contrasting growth patterns to the different influence of climate teleconnections, e.g.

413   between the eastern and western Mediterranean basin (Chen *et al.*, 2015; Seim *et al.*, 2015).

414

415   Numerous studies have demonstrated that mast years in many tree species are associated with

416   specific weather conditions ("weather cues") prior to mast events (Koenig & Knops, 2014;

417   Roland *et al.*, 2014), and particularly with summer temperatures one and two years prior to

418   masting (Schauber *et al.*, 2002; Kelly *et al.*, 2013). We found similar results in this study,

419   showing that a small number of weather variables act as strong cues for masting in almost all

420   European beech populations, despite large climatic, genetic, and environmental differences.

421   Indeed, individual NC where this typical set of cues was not detected were often based on a

422   limited number of observations. We found no substantial differences in these weather cues of

423   masting among regions or clusters using either correlation analysis (Fig. 4, Fig. S10) or

424   regression models (Fig. 5), nor any significant effect of latitude (Fig. S10). This demonstrated

425   that, across the distribution, the cues for masting are highly spatially consistent, with positive

426   correlations for MAX_{JUL-1} (and to a lesser degree MAX_{JUN-1}), and negative for MAX_{JUL-2} and

427   MAX_{JUN-2}, with some local specificities. Combining June and July clearly improved the

428   consistency of strong (and significant) correlations, as did using DeltaT as a synthetic index

429   of temperature differences from year to year (Kelly et al. 2013). In some cases, the seasonal

430   analysis accounted for regional differences in the strongest individual month; AT1-3 were

431   good examples, as they responded more strongly to June temperatures than July (in contrast

432   to most other chronologies). In particular, DeltaT led to improved correlations in cases where

13

433 correlations with $MAX_{summer-1}$ and $MAX_{summer-2}$ had the expected signal, but were both

434 relatively weak (e.g. DE2, PL2, PL4), or where one individual correlation was much stronger

435 than the other (e.g. DE1, DE2, DEE, SE2, FR6). In the regression models for the NUTS-1

436 with the most data, a large proportion of the variance was explained by summer temperature

437 in years -1 and -2, suggesting that other signals are not very important.

438

439 Therefore, we suggest that the observed spatial organization of masting is more dependent on

440 weather variation across space, rather than on different sensitivities of beech population to

441 the weather cues, in contrast to what Masaki *et al.* (2008) found for *Fagus crenata*. In other

442 words, traits related to masting seems to be the same across the whole beech distribution

443 range, with the exception of small regional differences – e.g., a shift of the most important

444 summer month along a latitudinal gradient, or an increased role of temperatures in the months

445 associated with flowering, pollination and seed maturation (Hase, 1964) in northern Europe.

446

447 While the well-known relationship between general summer weather and masting in beech

448 was well supported by our results, we were also able to disentangle the relative importance of

449 temperature and precipitation as the dominant cue of masting. Wachter (1964) and Piovesan

450 and Adams (2001) suggested that summer precipitation or drought, along with or rather than

451 temperature, were the main cue of masting in beech, while Drobyshev *et al.* (2010) found no

452 relationship between masting and summer precipitation or drought (but did find a strong

453 temperature signal). We have shown that summer precipitation in the two years prior to

454 masting was an important predictor of mast events in some regions (Fig. 4, Fig. 5), and that

455 summer drought was correlated with NC in some regions (Fig. S9), but that both precipitation

456 and drought were clearly of secondary importance to temperature as a cue of masting. An

457 additional analysis of the relationship between summer MAX and summer SPEI across

458 Europe showed correlations ranging from -0.3 to -0.5 (Fig. S12), suggesting that drought

459 could be more effective in predicting masting in certain locals than in others, hence the

460 contrasting evidence for previous year's drought effects in the literature. The effect of spring

461 precipitation appeared generally negligible, contrary to findings in more Mediterranean

462 species (Fernández-Martínez *et al.*, 2015). Additionally, the importance of precipitation did

463 not appear to vary systematically with latitude, e.g., in northern vs. southern regions where

464 summer drought stress may be limiting (average correlation between latitude and Spearman's

465 coefficient for MAX_{JUN-1}, MAX_{JUL-1}, and MAX_{AUG-1} = -0.13; MAX_{JUN-2}, MAX_{JUL-2}, and

466 MAX_{AUG-2} = 0.05; PRE_{JUN-1}, PRE_{JUL-1}, and PRE_{AUG-1} = 0.07; PRE_{JUN-2}, PRE_{JUL-2}, and

14

467 PRE_{AUG-2} = 0.09). Instead, summer temperatures in the previous two years, particularly in

468 July, were always the main cue of masting, with mast years associated with a cool summer

469 two years prior to masting, and warm temperatures in the summer prior to masting. This is

470 highly consistent with previous findings on the sensitivity to summer temperatures in both

471 *Fagus* and *Nothofagus* (two years prior: Gruber, 2003; Richardson *et al.*, 2005; Smaill *et al.*,

472 2011, Kelly *et al.*, 2013; one year prior: Hase, 1964; Wachter, 1964; Schauber *et al.*, 2002;

473 Suzuki *et al.*, 2005; Övergaard *et al.*, 2007; Masaki *et al.*, 2008). Recent analyses of the

474 climate sensitivity of beech diameter increment have also showed that cool, moist summers

475 have a positive effect on the growth of the same year, favoring a resource accumulation

476 hypothesis (Dorado Liñan *et al.*, 2017), while high summer temperatures have a negative

477 effect on growth of the following year throughout the whole geographic distribution,

478 including in northern and central regions (Hacket-Pain *et al.*, 2016), which could be

479 interpreted as a growth vs. reproduction tradeoff if masting was triggered in those years

480 (Monks and Kelly, 2006; Hacket-Pain *et al.*, 2015).

481

482 In addition to weather cues, we also found that masting was strongly affected by negative

483 temporal autocorrelation, i.e., masting category in the previous year (NC_{-1}). Ordinal logistic

484 regressions models were consistently able to predict mast years with accuracy (mean R^2 =

485 0.57) using summer temperature (and in some case precipitation) in the two previous years,

486 plus information on previous year's masting. Negative temporal autocorrelation with a lag of

487 one or two years is one of the defining characteristics of masting time-series (Davis, 1957;

488 Sork *et al.*, 1993; Selås *et al.*, 2002; Koenig *et al.*, 2003), and is the mathematical expression

489 of the rarity of consecutive mast years (category 4 or 5 in our dataset; consecutive years of

490 low masting category were instead common). The existence of negative autocorrelation in

491 masting time series has been traditionally interpreted as evidence for resource depletion, i.e.,

492 trees deplete most resources in the mast year, which limits reproduction in the following year

493 and makes consecutive heavy seed crops very rare (Davis, 1957; Sork *et al.*, 1993; Kelly &

494 Sork, 2002). However, recent studies have showed that negative temporal autocorrelation

495 would also emerge if masting were controlled by DeltaT only (Kelly *et al.*, 2013; Kon &

496 Saito, 2015; but see also Koenig *et al.*, 2015 for criticism of such model).

497

498 The strong correlations between masting and weather found by this study do not provide any

499 conclusive evidence to the debate on whether temperature is a "cue" for trees to trigger high

500 seed crops or whether it acts instead through intermediate steps indicative of a direct

15

501   mechanistic connection to seed production (Pearse *et al.*, 2014). Koenig & Knops (2000)

502   found that spatial autocorrelation in seed production of northern-hemisphere tree species

503   occurred at the same spatial scale as autocorrelation in rainfall and temperature, consistent

504   with the underlying effect of climatic factors on masting. However, they also found that seed

505   production had much higher variability than the weather factors, implying the existence of

506   non-linearities in weather effects, or of drivers for masting which remain unaccounted for.

507

508   While strong climate differences exist across the distribution of beech, the majority of

509   populations analyzed herein responded similarly to weather (e.g., negative response to

510   temperature and positive to precipitation two years before masting; Table 1). The negative

511   correlation with MAX_{JUL-2} could be related to resource accumulation in cooler years

512   ("priming" the trees to respond to increased temperature one year later, *sensu* Richardson *et*

513   *al.*, 2005), an interpretation that is consistent with a model of masting that includes an

514   element of carbon and/or nitrogen limitation (Sala *et al.*, 2012; Muller-Haubold *et al.*, 2015;

515   Monks *et al.*, 2016; Abe *et al.*, 2016; Pearse *et al.*, 2016). Indeed, a higher soil moisture due

516   to more precipitation and lower summer temperatures has been shown to increase litter mass

517   loss and N mineralization and uptake (Gessler *et al.*, 2005; Smaill *et al.*, 2011), which favors

518   masting in beech (Han *et al.*, 2014; Miyazaki *et al.*, 2014).

519

520   High temperatures in the summer prior to masting (MAX_{JUL-1}) have been linked to flower

521   primordia differentiation (Wachter, 1964; Gruber, 2003; see also: Merkle *et al.*, 1980 for

522   oaks, Allen *et al.*, 2014; Miyazaki *et al.*, 2014), in particular via an increase in endogenous

523   gibberellins (Turnbull, 2011; Pearse *et al.*, 2016). Following this reasoning, we might expect

524   the phenology of primordia differentiation to vary with latitude, creating a geographical

525   gradient in the timing of the previous summer cue similar to the pattern we found in some

526   southern European NUTS-1 (Fig. 4). Additionally, we also found correlations with weather

527   during the periods associated with other known processes that influence flowering

528   phenology, pollen production (Kasprzyk *et al.*, 2014; Pearse *et al.*, 2015), and seed

529   maturation in the year of masting, such as late winter frost (Matthews, 1955; Wachter, 1964),

530   at least in northern Europe. The resource priming in year$_{-2}$ can therefore interact with the

531   MAX cue in summer$_{-1}$ via a resource pulse that boosts an already favorable flower initiation.

532

533   Finally, the analysis of some of the longest series available showed that the sensitivity of

534   beech masting to the most important weather cues (MAX_{JUL-1} and MAX_{JUL-2}) was

16

535   substantially consistent through time in the last century (Fig. 6), with one possible exception

536   (DE9 with the strongest MCA trend of masting, and logistic model with poorest predictive

537   power). While many studies have reported associations between weather cues and mast years,

538   very few had the length of record required to test whether these cues are consistent through

539   time. Additionally, regression models fitted using data from the period 1950-2014

540   successfully described mast years in the first half of the 20th century (Fig. 5) – although we

541   did not switch the periods due to insufficient sample size for model calibration. This is an

542   important result, as there is little existing information on whether climate change affects the

543   sensitivity of masting to weather cues, or whether the timing of cues shifts seasonally as a

544   response to changing temperatures, as it has been demonstrated for leaf and flower phenology

545   (Menzel *et al.*, 2006). Assessing the effects of changing climate on the frequency and timing

546   of mast years is challenging (McKone *et al.*, 1998; Drobyshev *et al.*, 2014). Despite the

547   preeminent role of summer MAX, our analysis did not provide any strong evidence to

548   suggest that the relationships between weather and masting were sensitive to 20th century

549   warming (contrary to Övergaard *et al.*, 2007), as predicted by the theoretical model of Kelly

550   *et al.* (2013). This lends robustness to the attempts to reconstruct and predict mast years using

551   temperature data (e.g., Drobyshev *et al.*, 2014). However, this should be tested more

552   thoroughly. In particular, it is still unclear whether both gradual and abrupt (e.g., extreme

553   events) components of climate change influence masting frequency and spatial synchrony

554   within and across species or phylogenetic groups (Koenig *et al.*, 2016), for example through

555   changes in resource levels (Miyazaki, 2013; Allen *et al.*, 2014), pollen availability (Koenig *et*

556   *al.*, 2015), coexistence of species with different biomass allocation strategies (Perez-Ramos

557   *et al.*, 2015), and in the interactions between the processes of resource accumulation and

558   flower induction (Monks *et al.*, 2016).

871   **Figure legends**

872

873   **Fig. 1** (a) Current distribution of beech in Europe at 1-km resolution (Casalegno *et al.*, 2011,

874   filtered for cell cover >= 5%); (b) number of beech masting data series in each NUTS-1 for

875   the period 1950-2014.

876

877   **Fig. 2** (a) Mantel correlograms for NUTS-1 masting chronologies (1950-2014). Distance in

878   500-km wide bins. Black dots indicate significant (p ≤0.05) correlations, sequentially

879   corrected for multiple testing using Holm's procedure. (b) Pairwise Spearman's correlations

880   between NUTS-1 masting chronologies (1950-2014) against raw distance in km; black line:

881   local polynomial regression smoother.

882

883   **Fig. 3** Hierarchical clustering of NUTS-1 masting chronologies (1950-2014) based on

884   Suzuki's dissimilarity index (red: eastern cluster, green: northern, blue: southern, grey: no

885   data within beech distribution for the study period). © EuroGeographics for the

886   administrative boundaries. Output clipped on European beech distribution (Fig. 1a). Asterisks

887   indicate NUTS-1 used for analysis of long masting chronologies.

888

889   **Fig. 4** Spearman's correlation between monthly maximum temperature (1950-2014) and

890   NUTS-1 masting chronologies. NUTS-1 ordered and colored according to the cluster they

891   belong to (colors as in Fig. 3, black = excluded from clustering due to insufficient chronology

892   length). The three bottom lines show correlation against seasonal summer weather (June-

893   July) and the Delta variable (difference between weather variable in $year_{-2}$ and $year_{-1}$). The

894   sample size (number of years on record) is reported on the secondary x-axis. (.) significant at

895   p ≤0.05, (*) significant at p ≤0.00139 (Bonferroni-corrected). MEAN: the mean correlation

896   for the corresponding month across the study area.

897

898   **Fig. 5** Ordinal logistic models of masting (8 longest NC) as a function of weather predictors:

899   (a) model statistics for calibration (1950-2014) and validation (1901-1949). Rsq_1950_2014

900   is R^2 the calibration dataset, Rsq_boot is the bootstrapped R^2 from leave-one out cross-

901   validation (1000 re-samples), and Rsq_1901_1949 is the R^2 of the predicted values for 1901-

902   1949 vs. observed (validation dataset). (b) standardized model coefficients. Only significant

903   predictors are filled in the table, with the color depending on the coefficient.

904

32

905   **Fig. 6** Moving Spearman's correlation (lines: 28-years timesteps) between the eight longest

906   NC and MAX (1901-2014). Thick lines represent significant (p ≤0.05) correlations.

907

909

910 **Script S1** R Code for the analysis carried out in the present paper

911

912 **Table S1** NUTS-1 chronologies of masting from 1901 to 2016 on an ordinal scale of 1 (very

913 poor) to 5 (very abundant); dash = no data

914

915 **Table S2** Intra-NUTS correlation of masting series and temporal autocorrelation in NC (n =

916 records in the chronology, including only consecutive series of ≥ 7 records; rho = mean

917 Spearman's correlation between all series in the NUTS-1; ar1 = autoregression coefficient at

918 lag (1); slope=slope of linear regression of NC vs. time; n.s. = non-significant at p =0.05).

919

920 **Fig. S1** Mean Spearman's rank correlation of masting series within each NUTS-1 (black: no

921 data; grey: NUTS-1 with less than 2 series or <7 years' overlap between series). ©

922 EuroGeographics for the administrative boundaries

923

924 **Fig. S2** NUTS-1 masting chronologies from year 1976 to 2014 (black: no data; grey: no data

925 for the year; orange: very poor [1]; dark green: very abundant [5]). Output clipped on beech

926 distribution (Fig. 1a)

927

928 **Fig. S3** Mantel correlograms for NUTS-1 masting chronologies (1950-2014) across latitude

929 (left) and longitude only (right). Black dots indicate significant correlations (p ≤ 0.05),

930 sequentially corrected for multiple testing using Holm's procedure.

931

932 **Fig. S4** Dendrogram for the hierarchical clustering of NUTS-1 masting chronologies (1950-

933 2014)

934

935 **Fig. S5** Spearman's correlation between monthly mean temperature (1950-2014) and NUTS-

936 1 masting chronologies. NUTS-1 are ordered and colored according to the cluster they belong

937 to (colors as in Fig. 3, black = excluded from clustering due to insufficient chronology

938 length). The three bottom lines show correlation against seasonal summer weather (June-

939 July) and the Delta variable (difference between weather variable in year$_{-2}$ and year$_{-1}$). The

940 sample size (number of years on record) is reported on the secondary x-axis. (.) significant at

34

941   p ≤0.05, (*) significant at p ≤0.00139 (Bonferroni-corrected). MEAN: the mean correlation

942   for the corresponding month across the study area

943

944   **Fig. S6** Spearman's correlation between monthly minimum temperature (1950-2014) and

945   NUTS-1 masting chronologies. NUTS-1 are ordered and colored according to the cluster they

946   belong to (colors as in Fig. 3, black = excluded from clustering due to insufficient chronology

947   length). The three bottom lines show correlation against seasonal summer weather (June-

948   July) and the Delta variable (difference between weather variable in year$_{-2}$ and year$_{-1}$). The

949   sample size (number of years on record) is reported on the secondary x-axis. (.) significant at

950   p ≤0.05, (*) significant at p ≤0.00139 (Bonferroni-corrected). MEAN: the mean correlation

951   for the corresponding month across the study area

952

953   **Fig. S7** Spearman's correlation between monthly precipitation (1950-2014) and NUTS-1

954   masting chronologies. NUTS-1 are ordered and colored according to the cluster they belong

955   to (colors as in Fig. 3, black = excluded from clustering due to insufficient chronology

956   length). The three bottom lines show correlation against seasonal summer weather (June-

957   July) and the Delta variable (difference between weather variable in year$_{-2}$ and year$_{-1}$). The

958   sample size (number of years on record) is reported on the secondary x-axis. (.) significant at

959   p ≤0.05, (*) significant at p ≤0.00139 (Bonferroni-corrected). MEAN: the mean correlation

960   for the corresponding month across the study area

961

962   **Fig. S8** Spearman's correlation between monthly SPI3 (1950-2014) and NUTS-1 masting

963   chronologies. NUTS-1 are ordered and colored according to the cluster they belong to (colors

964   as in Fig.3, black = excluded from clustering due to insufficient chronology length). The

965   three bottom lines show correlation against seasonal summer weather (June-July) and the

966   Delta variable (difference between weather variable in year$_{-2}$ and year$_{-1}$). The sample size

967   (number of years on record) is reported on the secondary x-axis. (.) significant at p ≤0.05, (*)

968   significant at p ≤0.00139 (Bonferroni-corrected). MEAN: the mean correlation for the

969   corresponding month across the study area

970

971   **Fig. S9** Spearman's correlation between monthly SPEI3 (1950-2014) and NUTS-1 masting

972   chronologies. NUTS-1 are ordered and colored according to the cluster they belong to (colors

973   as in Fig. 3, black = excluded from clustering due to insufficient chronology length). The

974   three bottom lines show correlation against seasonal summer weather (June-July) and the

35

975 Delta variable (difference between weather variable in year$_{-2}$ and year$_{-1}$). The sample size

976 (number of years on record) is reported on the secondary x-axis. (.) significant at p $\leq$0.05, (*)

977 significant at p $\leq$0.00139 (Bonferroni-corrected). MEAN: the mean correlation for the

978 corresponding month across the study area

979

980 **Fig. S10** Linear models of Spearman's correlation between masting and MAX in June, July,

981 or August of the one and two years prior vs. latitude, in all NUTS-1 anayzed. Black dots are

982 significant correlations, grey dots non-significant ones. Confidence intervals computed at

983 p=0.05. Boxplots represents the number of NUTS-1 where Spearman's correlation between

984 masting and MAX is highest in selected summer months; width of the boxplots is

985 proportional to sample size.

986

987 **Fig. S11** Summary of moving Spearman's correlation (1901-2014, window size: 28 years)

988 between the eight longest NC and MAX$_{JUL-1}$ (red) and MAX$_{JUL-2}$ (blue). Timestep is one

989 year. The colored area in each violin plot represents the range of correlation values and is

990 shaped by a kernel density estimator, the dots represent correlation value with a color

991 intensity proportional to the significance of correlation estimated by bootstrapping

992 (significant at p $\leq$0.05: more intense). Larger dots represent the median correlation value.

993

994 **Fig. S12** Spearman's correlation between MAX in June-July and SPEI3 across the study area,

995 period 1901-2014 (black: no data). © EuroGeographics for the administrative boundaries.

996

997 **Fig. S13** Hierarchical clustering of NUTS-1 weather variables (1950-2014) based on

998 Suzuki's dissimilarity index (red: eastern cluster, green: northern, blue: southern, grey: no

999 data within beech distribution for the study period). © EuroGeographics for the
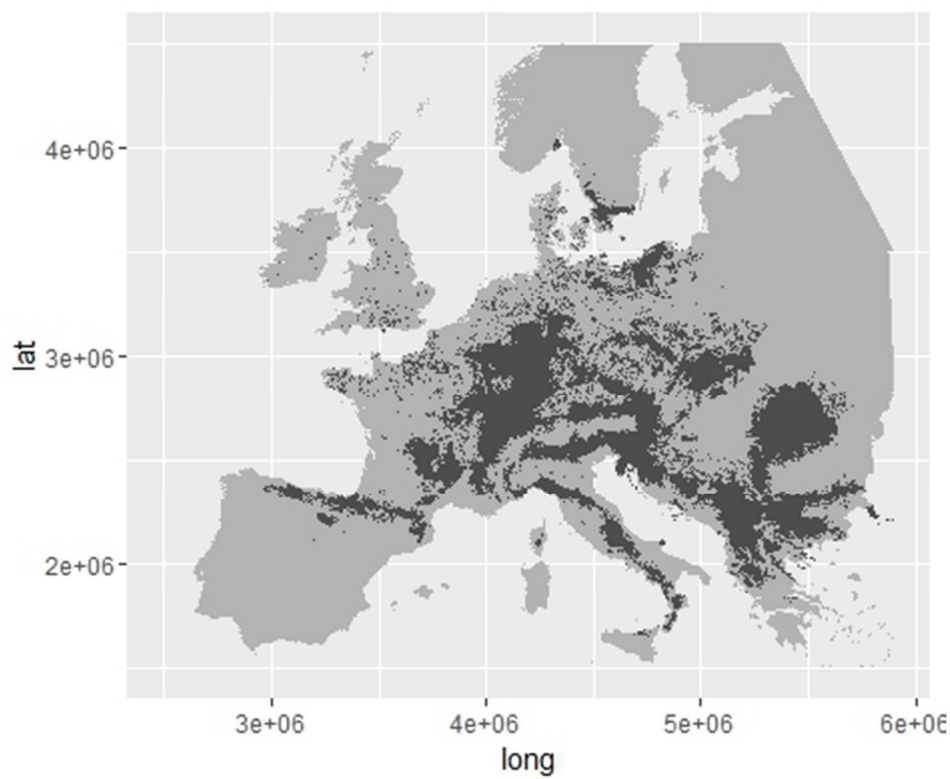

1000 administrative boundaries.
