1 **Abstract**

2 The cleaner-client system among reef teleosts has received considerable attention in both wild and  
3 captive environments, but the spatially and taxonomically diverse associations between cleaner  
4 fish and elasmobranchs are less understood. Using remote video, we investigated interactions  
5 between giant manta rays (*Mobula birostris*) and cleaner wrasse at a seamount in the Philippines.  
6 Cleaning events occurred between 11:00 and 16:00 hours on a seasonal basis and were constrained  
7 by current strengths and ambient water temperatures. The frequency with which giant manta rays  
8 interacted with cleaner fish varied on an individual basis. Blue streaked cleaner wrasse (*Labroides*  
9 *dimidiatus*) and moon wrasse (*Thalassoma lunare*) selectively foraged on manta rays' gills and  
10 pelvis, with *L. dimidiatus* also demonstrating slight preferences for the pectoral fins. Cleaners'  
11 foraging preferences may indicate ectoparasitic infections in specific areas of a manta ray's body.  
12 The exclusivity with which giant manta rays visited a particular cleaning station on the seamount  
13 may be a response to the quality of services that cleaners provide there. Giant mantas' fidelity to  
14 this site may also be attributed to localised concentrations of food that are available nearby. The  
15 seamount provides habitat that appears to be important to the life history strategies of the region's  
16 giant manta rays.

## 26 **Introduction**

27 Seamounts are widely regarded as hotspots of biodiversity due to the unique oceanographic  
28 conditions that they generate (Morato et al. 2010, Clark et al. 2010), and have been identified as  
29 important staging areas for migrant marine megafauna (Worm et al. 2003, Pitcher et al. 2010).  
30 While the ecological mechanisms that attract elasmobranchs to seamounts are poorly understood,  
31 it has been suggested that they provide refuge, represent social convergence points, act as  
32 navigational waypoints, and function as mating, feeding, and nursery grounds for a variety of  
33 pelagic species (Worm et al. 2003, Pitcher et al. 2010, Oliver & Bicskos 2014, Wells et al. 2018).

34

35 The giant manta ray (*Mobula birostris*) is one of two recognised manta ray species (Marshall et al.  
36 2009). Reaching 6.70 m in total (disc) width, the ray is popular among tourists for its size and  
37 approachable behaviour. Recognised from fisheries and by-catch to frequent tropical and  
38 subtropical offshore waters circumglobally, giant manta rays mature late, have low fecundity, and  
39 are classified as Vulnerable to Extinction by the International Union for the Conservation of Nature  
40 and Natural Resources' (IUCN) Red List of Species (Marshall et al. 2018). For the past two  
41 decades, giant manta rays have been observed by SCUBA divers on Monad Shoal, which is a  
42 shallow coastal seamount in the Central Visayas of the Philippines, where they interact with blue  
43 streaked cleaner and moon wrasse (*Labroides dimidiatus* and *Thalassoma lunare*) (Acebes et al.  
44 2016). Rays, including giant manta rays, are known to host metazoan parasites (Caira and Healy  
45 2004), and it is proposed that they visit a cleaning station at this site to control infection.

46

47 Batoid rays infected with parasites suffer a variety of health consequences. These include skin  
48 lesions, necrosis, anaemia, respiratory disease, and chronic bacterial and viral infections that have  
49 been reported as lethal in some species (Caira and Healy 2004, Garner 2013). Ectoparasitic  
50 infections in captive elasmobranchs cause behavioural modifications such as rubbing against the

51 structures of enclosures and interacting with cleaner fish (Keyes 1982, Reed et al. 2009).  
52  
53 The cleaning system is a classic model of cooperative behaviour among species in which cleaner  
54 fish remove ectoparasites and dead or infected tissue from the surface, gills and sometimes the  
55 mouth of client fish (Soares 2017). Interactions with cleaner fish appear to improve the health of  
56 teleost clients by reducing their ectoparasite loads, but the benefit of these interactions is less  
57 understood amongst elasmobranchs (Grutter 1996, Grutter and Lester 2002, Waldie et al. 2011,  
58 Soares et al. 2011, Ros et al. 2011). Clients will often ‘pose’ near cleaning stations to solicit  
59 ‘services’ from cleaner fish (Bshary and Côté 2008, Oliver 2012). There are approximately 130  
60 species of marine cleaners, with ectoparasitic infection being the most likely proximate cue for  
61 clients seeking their services (Keys 1982, Sikkell et al. 2004, Oliver et al. 2011). The blue streaked  
62 cleaner wrasse, *Labroides dimidiatus*, is an obligate cleaner that preferentially feeds on gnathiid  
63 isopod larvae that are known to infect the gills of reef manta rays (*Mobula alfredi*) (Grutter 1996,  
64 Grutter and Bshary 2004, Marshall 2009, O’Shea et al. 2010). *L. dimidiatus* prefer large clients  
65 and interact with manta rays at spatially diverse locations across the globe (Grutter 1996, Grutter  
66 et al. 2005, Marshall 2009, Kitchen-Wheeler 2010, Germanov et al. 2019). The moon wrasse,  
67 *Thalassoma lunare*, which is less understood as a cleaner species, also provides cleaning services  
68 for manta rays (Kitchen-Wheeler 2010, Barbu et al. 2011, Germanov et al. 2019). Moon wrasse  
69 are facultative cleaners wherein only juveniles clean whilst contemporaneously exploiting  
70 alternative food sources (Côté 2000).

71  
72 Cleaners may maximize the profitability of their energy return by selectively foraging on areas of  
73 clients where specific types of parasites can be found (Rohde 2005). When investigating how  
74 cleaners forage on elasmobranchs, Oliver et al. (2011) showed that *L. dimidiatus* and *T. lunare*  
75 spent more time inspecting areas of thresher sharks (*Alopias pelagicus*) that were infected by

76 ectoparasitic digeneans (*Paronatrema spp*) compared to areas that are known to harbour other  
77 types of parasites (Cadwallader et al. 2015). They concluded that cleaners may optimise their  
78 foraging by selecting areas of a client's body that are most likely to produce the highest energy  
79 reward per unit effort (Rohde 2005, Oliver et al. 2011). A cleaner's foraging behaviour is therefore  
80 likely to be driven by the quality of the food patch in relation to the ease with which food may be  
81 obtained there (Oliver et al. 2011). Since specific types of parasites infect specific patches of an  
82 elasmobranch's body (Caira and Healy 2004, Rohde 2005), it can be predicted that cleaners will  
83 show preferences for foraging in some patches over others.

84

85 In this paper we show that giant manta rays (*M. birostris*) interact with cleaners at a seamount in  
86 the Philippines and investigate the cleaner-client association. We quantified behavioural  
87 interactions between giant manta rays and cleaner wrasse from remote video observations to  
88 address the following hypotheses: (1) the dynamics of the cleaner-manta system are driven by  
89 environmental factors; and (2) cleaner wrasse preferentially forage on specific areas of a manta  
90 ray's body. The cleaner-manta association is discussed in relation to other known cleaner-client  
91 systems in the marine environment.

92

## 93 **Method**

### 94 *Location*

95 Monad Shoal (N 11° 19' 06.7", E 124° 11' 31.9") is a seamount in the Central Visayan Sea, near  
96 Malapascua Island, Cebu, the Philippines (Oliver et al. 2011). The top of the mount (15 – 25 m) is  
97 formed by a shallow plateau of low-profile *Acropora* that is fringed on all sides by a coral reef  
98 which crests and sheers down 250 m to the valley below. An array of cleaning stations lines the  
99 southern face of the mount, one of which (Station A) is frequented by giant manta rays (Oliver et  
100 al. 2011).

101 *Sampling*

102 SCUBA divers initially deployed remote video cameras using protocols described by Oliver et al.  
103 (2011) at five cleaning stations (A - E) on Monad Shoal during a pilot study which ascertained that  
104 Station A was the only location on the seamount where giant manta rays could be observed  
105 interacting with cleaner fish. A total of 1,171.45 hours of video observations were subsequently  
106 recorded from a fixed point on Station A between April 2011 and June 2013, during three field  
107 expeditions spanning 262 days over 20 months. A Sony Handycam® HDR-SR8, housed in an  
108 Amphibico Elite housing and fitted with a 120° wide-angle lens, with focal range locked to 0.3 m,  
109 was pre-set to record for 360 continuous minutes for all camera deployments. The camera was  
110 retrieved at the end of each deployment period, and the video data downloaded for analysis.

111

112 Environmental data including tidal conditions, water temperature, and the *in situ* current strength  
113 were documented for each camera deployment. Temperature was measured *in situ* to the nearest  
114 degree Celsius using the readouts of a dive computer at the time of the camera deployment. Current  
115 strength was measured from a submerged windsock that was fixed to the substrate in the camera's  
116 field of view. Tides were estimated from Admiralty predictions for Bogo Bay, the Philippines  
117 (EasyTide 2011-2013).

118

119 *Analysis of video recordings*

120 Video observations of giant manta rays were analysed in 29.97 frames s<sup>-1</sup> resolution using Final  
121 Cut Pro 7 (Apple Inc. CA). Sequences documenting interactions between manta rays and wrasse  
122 were classified as cleaning 'events'. These began when a manta ray entered the camera's field of  
123 view and ended after it left and did not return for  $\geq 5$  minutes. If an individually identified manta  
124 (see section below) returned during this time period it was considered to be a continuation of the  
125 cleaning event. Because it was not possible to scale a manta ray from its distance to the camera,

126 size was not considered in the analyses. Sex was determined through the presence or absence of  
127 claspers.

128

### 129 *Identification of individual manta rays*

130 We took still images of the video recordings when a manta ray was positioned directly above the  
131 camera to capture its ventral surface. We then entered the still images into a photo bank that  
132 considered patterning in the manta's ventral markings to identify a new individual, or a match to  
133 an individual that had been previously observed at Station A following Marshall et al. (2011) and  
134 Town et al. (2013). Due to the camera's field of view, it was not always possible to capture the  
135 entire ventral surface for each manta ray so some mantas could not be individually identified.

136

### 137 *Cleaning interactions*

138 To investigate whether cleaners forage selectively on giant manta rays, it was assumed that  
139 different areas of a client's bodyscape host different types of parasites (Caira and Healy 2004,  
140 Rohde 2005), and that some areas represent higher quality food patches for cleaners than others  
141 (Bshary and Grutter 2002, Oliver et al. 2011). Eight food patches were outlined on a sketch of a  
142 giant manta ray and categorised as 'gills', 'pelvis', 'dorsal head', 'ventral head', 'pectoral',  
143 'ventral body', 'dorsal body', and tail (Fig. 1). These were then used to document cleaner  
144 interactions for each event. The pelvic and tail patches included the cloaca and tail respectively,  
145 the pectoral patch incorporated both pectoral fins, the gill patch included both sets of gill openings,  
146 and the head patch consisted of the cephalic lobes, the eyes, and the mouth. The ray's dorsal  
147 surface was split into two patches, the boundary of which followed the underside of the ray's  
148 superbranchial region (Fig. 1).

149

150 Cleaning interactions were characterised by a cleaner's mouth making discernible physical contact

151 with a manta ray and were termed 'bites'. Bite locations were individually mapped onto the sketch  
152 according to their associated cleaner species (*Labroides dimidiatus* or *Thalassoma lunare*) and  
153 treated separately in the analyses. Bites were used as a proxy for parasite removal following Oliver  
154 et al. (2011). The number of cleaning inspections may be underestimated because cleaner fish  
155 activity behind a manta ray could not be observed on the video recordings.

156

### 157 *Statistical Analyses*

158 To investigate variation in the distribution of manta ray visits to the cleaning station, a generalized  
159 additive model was fitted with a binomial error distribution. The response variable was manta ray  
160 presence, or absence, in any given minute during which the camera was recording. The effects of  
161 the explanatory variables day of the year, minutes after high tide, minutes after 05:00 and current  
162 strength (m/s) were modelled by thin-plate cubic splines. Knots were conservatively set to three  
163 unless we believed there to be more degrees of freedom in the relationship, in which case knots  
164 were increased until no further changes were visible when plotting the output (Wood 2017), which  
165 occurred in the cases of day of the year ( $k = 12$ ), and minutes after high tide ( $k = 4$ ). Temperature  
166 ( $^{\circ}\text{C}$ ), and minutes observed, were also included as explanatory variables, but with only a linear  
167 effect since they took too few distinct values to allow a more complex approach.

168

169 To investigate variation in the rate of cleaning interactions, a hierarchical Poisson regression model  
170 was fitted. The number of interactions observed in a cleaning event was the response variable, with  
171 day of the year, minutes after high tide, temperature ( $^{\circ}\text{C}$ ), minutes after 05:00, manta ray identity  
172 term, and current strength (m/s) as quantitative explanatory variables. We included an offset term  
173 representing the natural log of event time in seconds, under the assumption that the expected  
174 number of interactions over the duration of an event was the product of the rate of interactions per  
175 second, and the total event time. Event number was included as a normally-distributed random

176 intercept term with a mean of zero and an unknown standard deviation, to account for differences  
177 between events in the rate of interactions.

178

179 To determine how cleaner wrasse foraging differed between patches on a manta ray, another  
180 hierarchical Poisson regression model was fitted. The number of cleaning interactions on a given  
181 patch of a given manta ray by a given cleaner species was modelled as a random variable with a  
182 Poisson distribution. The natural log of the expected number of interactions per unit area (where  
183 the unit is the entire surface area of a manta) was modelled as a linear function of patch, cleaner  
184 species, and the interaction between patch and cleaner species. To control for differences in patch  
185 size, the expected number of interactions per unit area was multiplied by the proportion of body  
186 surface area that each patch represents. These area proportions were estimated by counting pixels  
187 in each patch on a perpendicular image of a manta ray's dorsal and ventral surfaces in Adobe  
188 Photoshop (Adobe Inc, San Jose, California). The effects of event number on the natural log  
189 number of inspections were assumed to be drawn from a normal distribution with mean zero and  
190 an unknown standard deviation. To examine whether each species of cleaner wrasse preferred  
191 specific patches after controlling for patch area, back-transformed patch effects with central 95%  
192 credible intervals were calculated for each cleaner species. These estimates were expressed  
193 graphically relative to the preference for the dorsal head patch, with overlapping credible intervals  
194 between species indicating that there was not a clear difference in preference.

195

196 All analyses were completed in the R statistical environment (R Core Team, 2019), using the  
197 rstanarm package (Goodrich et al. 2018), which implements the NUTS algorithm for Bayesian  
198 inference (Gelman et al. 2013). Generic weakly informative priors (independent normal (0, 1))  
199 (Gelman et al. 2015) were used for all parameters. For each model, four Monte Carlo chains were  
200 run for 2500 warmup iterations followed by 2500 sampling iterations. Potential scale reduction

201 factors ( $\hat{R}$ ) were  $< 1.1$  for all parameters and effective sample sizes ( $n_{\text{eff}}$ ) were greater than 2500,  
202 indicating no problems with model convergence. To assess model fits, PSIS-LOO values were  
203 computed in the loo package (Vehtari et al. 2017). Pareto  $k$  diagnostics and marginal posterior  
204 predictive checks were undertaken using the bayesplot package (Gabry et al. 2018) which did not  
205 reveal any obvious issues (PSIS  $\hat{k} < 0.7$  and no evidence of overdispersion). Initial models were  
206 simplified through term by term deletions, operating under the assumption that a negative  
207 difference in ELPD values of more than 2 estimated standard deviations indicated a worse model.

208

## 209 **Results**

### 210 *Event Frequency*

211 We identified 15 individual manta rays from 154 cleaning events that were recorded over 60 days  
212 during 15 of the study months (April 2011 - June 2013). Individual mantas were observed  
213 interacting with cleaners for a mean ( $\pm$  SE) of  $4.4 \pm 0.22$  events (95% CI: 4.18-4.62), and events  
214 lasted  $5.23 \pm 0.97$  minutes (95% CI: 5.06-5.56 minutes).

215

216 Nine mantas (M2 - M10) were first recorded in 2011, four of which were observed revisiting the  
217 site in 2012 (M5, M7, M8, M9). Six mantas (M11 - M16) were first observed in 2012, two of  
218 which (M12, M13) were observed revisiting the site in 2013. One manta (M9) was observed every  
219 year (2011 - 2013). Across all observations four manta rays were only seen on a single occasion.  
220 The remaining eleven ( $\pm$  SE) had a return rate of  $5.64 \pm 0.27$  (95% CI: 5.10 - 6.18) across the three  
221 observation years.

222

223 Comparisons between models of giant manta ray visits showed that the minutes observed, and the  
224 minutes after the high tide explanatory variables should be omitted from the final model (Table 1).  
225 Manta ray visits to the cleaning station varied throughout the year, occurring most frequently

226 between April and September, with visits rare during March and July (Fig. 2(a), Table 2). Visits  
227 were most likely to occur during warmer temperatures (Fig. 2(b) and in the afternoon (Fig. 2(c),  
228 Table 2). Visits were also most likely to occur when the current was strong ( $> 1.5$  m/s) or weak ( $\sim$   
229  $0.2$  m/s -  $0.4$  m/s), but they were rare when the current was mild ( $\sim 1$  m/s) (Fig. 2(d), Table 2).

230

### 231 *Cleaning Interactions*

232 There were 32 recorded cleaning events by 11 identifiable mantas for which all data was available.  
233 These events lasted between 41 and 2976 seconds (mean: 1087 seconds) and involved between 1  
234 and 22 discernible cleaning interactions (mean: 4.91). Comparisons between single term deletions  
235 of the model for cleaning interactions indicated that all of the explanatory variables should remain  
236 in the final model (Table 3).

237

238 The rate of interactions varied between individual manta rays (Fig. 3(b); Table 4), with some (for  
239 example M8) receiving much more attention from cleaners than others. The current strength was  
240 found to constrain the number of interactions a manta ray received (Fig. 3(d)), and higher water  
241 temperatures had a weakly positive effect (Fig. 3(e) Table 4). The minute after 05:00 had a weak  
242 negative effect (Fig. 3(a), and the day of the year had a weakly positive effect (Fig. 3(f); Table 4).

243

### 244 *Patch Preference*

245 Single term deletions of the model for patch preferences by cleaner species indicated that the  
246 interaction between the patch and species should be omitted from the final fitted model (Table 5).  
247 After controlling for differences in patch area and comparing each patch to the 'dorsal head',  
248 cleaners showed preferences for certain patches (Fig. 4, Table 6). Both species targeted the gills,  
249 which received the largest absolute number of cleaning interactions, with both cleaner species also  
250 showing a preference for the pelvis (Fig. 4; Table 6). The pectoral fins received large absolute

251 numbers of cleaning interactions by *L. dimidiatus*, which resulted in a slight preference for this  
252 patch by this species despite its large value for patch proportion (Fig. 4; Table 6). *T. lunare*'s  
253 preference for the ventral body could not be estimated since no cleaning interactions were recorded  
254 in this patch for this species, even though this parameter was structurally identifiable in the analysis  
255 (Table 7).

256

## 257 **Discussion**

258 While the cleaner-client system amongst reef teleosts has received considerable attention, the  
259 spatially and taxonomically diverse associations between cleaners and elasmobranchs are less  
260 understood (Couturier et al. 2018, Grutter et al. 2018). This study represents the first attempt to  
261 quantify interactions between giant manta rays and cleaner wrasse in the natural environment and  
262 supports knowledge of the importance of cleaning stations to marine ecosystems.

263

### 264 *Visit Frequency*

265 Our observations of giant manta rays were most likely to occur in the afternoon on a seasonal basis  
266 between the months of April and September. Giant manta rays' large body size and planktivorous  
267 diet make ocean productivity a key factor in determining their movements (Papastamatiou et al.  
268 2012, Braun et al. 2014, Burgess et al. 2016), and seasonal shifts in food availability encourage  
269 them to undertake substantial migrations (Dewar et al. 2008, Papastamatiou et al. 2012, Burgess  
270 et al. 2016). Giant manta rays are known to frequent cleaning stations in Mozambique, Ecuador,  
271 and Indonesia during the austral winter (Dewar et al. 2008, Rohner et al. 2013, Burgess et al. 2016),  
272 and their seasonal fidelity to these sites has largely been attributed to increases in local productivity  
273 (Carleton et al. 2001, Pitcher et al. 2008) that is driven by oceanographic processes, including  
274 currents (Dewar et al. 2008, O'Shea et al. 2010, Jaine et al. 2012, Rohner et al. 2013, Burgess et  
275 al. 2016). It is possible that giant manta rays have limited movements on a regional scale in our

276 study area and that they are only in the vicinity of Monad Shoal when seasonal oceanographic  
277 processes promote shifts in productivity and the consequent availability of food (Stewart et al.  
278 2016). They may partition their time to converge on Station A during the afternoon when food is  
279 scarce and/or when hydrodynamic conditions facilitate cleaning (see below) (Johansen et al. 2008,  
280 Marshall et al. 2011). Similar temporal trends for giant manta rays visiting cleaning stations have  
281 been observed in Indonesia where they are known to move offshore to forage nocturnally in deep  
282 waters after they clean (Dewar et al. 2008). Mantas' movements and use of our study area may be  
283 part of a strategy that considers both temporal variations in food availability and cleaner services  
284 without being mutually exclusive (Burgess et al. 2016, Oliver et al. 2019).

285

286 The overall occurrence of giant manta ray cleaning events was strongly influenced by the state of  
287 the current on the seamount. Certain hydrodynamic conditions may generate sufficient water flow  
288 and lift for giant mantas to 'hover' over specific topographical features (Johansen et al. 2008,  
289 Marshall et al. 2011). In Mozambique reef manta rays are known to clean during moderate strength  
290 currents because these conditions are favourable for hovering over cleaning stations (Rohner et al.  
291 2013). Hovering may facilitate giant mantas' interactions with cleaners since cleaning typically  
292 occurs near spatially finite structures that are known as 'focal points' (Acebes et al. 2016, Stevens  
293 et al. 2018). Hovering is also likely to be an energetically efficient strategy that makes giant manta  
294 rays more accessible to cleaners and therefore more attractive as clients (Acebes et al. 2016, Fish  
295 et al. 2018). However, even though hydrodynamic flow may provide lift and facilitate a giant  
296 manta's hovering behaviour over a cleaning station, cleaning events were not observed on Monad  
297 Shoal when the current was strong. Cleaners are known to seek refuge and conserve their energy  
298 during strong currents, which stalls the provision of cleaning services for their clients (Johansen  
299 et al. 2008, Eggersten et al. 2016). The reduced availability of cleaners may have decreased the  
300 likelihood of a giant manta ray visiting the site during these periods in spite of the energetic

301 benefits provided by strong currents (Tebbich et al. 2002, Johansen et al. 2008, Fish et al. 2018).

302

### 303 *Cleaning Interactions*

304 Reef teleost clients are known to show preferences for specific services that are offered by specific  
305 cleaners at specific stations (Bshary and Grutter 2006, Pinto et al. 2011). A client's fidelity to  
306 individual cleaners may be driven by the type and quality of service on offer (parasite removal,  
307 wound healing, tactile stimulation), or other clients competing for the same resources (Bshary and  
308 Grutter 2006, Bshary et al. 2008, Adam 2010). Many of the individual mantas that we observed  
309 on Station A had open wounds from bite marks and dismembered cephalic lobes, presumably from  
310 encounters with predators and/or fishing gear (Oliver 2012). Giant manta rays' fidelity to this site  
311 may be indicative of a lack of competition from other elasmobranch clients, and/or specialist  
312 wound healing and parasite removal services that are on offer at this particular location.

313

314 Higher temperatures were found to influence the frequency with which giant manta rays visited  
315 Station A and were also associated with an increase in the frequency of their interactions with  
316 cleaners. Digenean flatworms (Phylum Platyhelminthes) that are known to infect the cloacas of  
317 elasmobranchs on Monad Shoal (Caira and Healy 2004, Oliver et al. 2011, Cadwallader et al.  
318 2015) are typically dioxenous, parasitising two hosts during their life cycle (Mills 1979). During  
319 reproduction, oviparous digeneans release their fertilised eggs into the water column where they  
320 hatch to produce miracidia. The miracidia swim to find an intermediate mollusc host where they  
321 grow through several life stages until they eventually emerge as cercaria larvae (Gibson et al.  
322 2002). Larvae live freely in the water column before they attach to their terminal host, which they  
323 locate from host-derived chemical or mechanical cues, or shadows (Whittington et al. 2000).  
324 Attachment typically occurs during seasonal epizootic events, which are characterised by cool (~  
325 25 °C) or warm (~ 32 °C) water conditions (Whitfield et al. 1977) and may coincide with a time

326 when hosts are particularly vulnerable to infection (Möller 1978, Silan et al. 1985, Tubbs et al.  
327 2005, Rückert et al. 2008). We conjecture for further study that the seasonality with which giant  
328 manta rays visit Monad Shoal might coincide with ectoparasite attachment events in the area,  
329 leading to heightened parasitism and a greater need for interacting with cleaners.

330

331 Since cleaner fish tend to modify their foraging patterns in response to variations in the quantity  
332 and quality of a food resource, giant manta rays with the highest parasite loads are more likely to  
333 be attractive clients (Oliver et al. 2011, Pinto et al. 2011). *L. dimidiatus* typically favours larger  
334 clients with high ectoparasite infections, and a client's body size has been positively correlated  
335 with ectoparasite abundance (Barber et al. 2000, Sikkell et al. 2000, Grutter and Bshary 2003, Caira  
336 and Healy 2004). The number of cleaning interactions (per unit time) varied substantially among  
337 individual mantas across our observations. Although we were not able to quantify body size, it is  
338 possible that larger mantas received more attention from cleaners than smaller ones (Sikkell et al.  
339 2000, Grutter and Bshary 2003, Oliver et al. 2011).

340

341 Cleaning interactions were patch-specific, suggesting that the cleaners forage selectively across a  
342 giant manta ray's bodyscape. Ectoparasites that attach to elasmobranchs are site specific and  
343 typically infect the same sites across different host species (Littlewood et al. 1997, Henderson et  
344 al. 2002, Caira and Healy 2004, Dippenaar et al. 2008). Platyhelminthes parasitise most  
345 elasmobranchs (Caira and Healy 2004), and *Paronatrema spp* found in and around the cloaca of  
346 pelagic thresher sharks (*Alopias pelagicus*) that regularly visit our study site are thought to be the  
347 primary driver for cleaners preferentially foraging on their pelvis (Oliver et al. 2011, Cadwallader  
348 et al. 2015). Monogenean flatworms are similarly known to infect the cloaca of manta rays in  
349 Mozambique (Marshall 2009), and gnathiid isopods, which are a primary food source for the blue  
350 streaked cleaner wrasse, infect their buccal cavities (Grutter and Poulin 1998, Marshall 2009).

351 While it was not possible to verify whether manta rays visiting Monad Shoal are infected by  
352 gnathiids, digeneans, or monogeneans, our observations suggest that either parasitic abundance is  
353 highest in and around the cloaca and gills, or that cleaner fish are selecting parasites, mucus, and/or  
354 dead tissue there because they are accessible.

355

#### 356 *Concluding remarks*

357 Many large marine organisms visit cleaning stations to have parasites removed and giant manta  
358 rays appear to regularly visit cleaning stations on inshore reefs. The rays may visit cleaning stations  
359 to benefit from feeding opportunities nearby or they may migrate inshore to clean after they forage  
360 in deep-water (Burgess et al. 2016, Stewart et al. 2016). Giant manta rays are thought to have  
361 limited regional connectivity and so the low number of absolute visits that we recorded either  
362 suggests that the habitat no longer supports their requirements, or that they are in regional decline  
363 (Stewart et al. 2016). Cleaning interactions are both spatially and taxonomically diverse and  
364 cleaners' selective foraging on giant manta ray clients demonstrates a level of preference for areas  
365 of a manta's body where specific types of parasites might be found. Future identification and  
366 quantification of parasite loads on giant manta rays would offer further evidence that elasmobranch  
367 clients provide high quality food patches for cleaners at seamounts. Cleaning stations are key  
368 points of convergence for giant manta rays and they may only frequent specific cleaning stations  
369 so these spatially finite habitats should be carefully managed.

370

#### 371 **Acknowledgements**

372 We are particularly grateful to the Governor of the Province of Cebu, and the Municipal Mayor of  
373 Daanbantayan for their support and guidance. We thank the staff and volunteers of the Thresher  
374 Shark Research and Conservation Project, Gary Cases, and Divelink Cebu for their field and  
375 technical support. We are also grateful to Thomas Grotheus for editorial input.

376 **Author contributions**

377 SO conceived and performed the experiments. CM and MS analysed the data. CM wrote the first  
378 draft as part of his undergraduate dissertation. SO, CM and MS wrote the final manuscript. All  
379 applicable international, national, and/or institutional guidelines for the care and use of animals  
380 were followed.

381

382 **Funding**

383 This work was funded by the Thresher Shark Research and Conservation Project. The funding  
384 body did not influence the design of the study and collection, analysis, and interpretation of the  
385 data nor the writing of the manuscript.

386

387 **Compliance with ethical standards**

388 *Conflicts of interest*

389 The authors declare that they have no conflicts of interests.

390

391 *Ethical standards*

392 The research presented in this paper complies with the guidelines from the directives 2010/63/EU  
393 of the European parliament and of the Council of 22nd September 2010 on the protection of  
394 animals used for scientific purposes. All of the fieldwork was undertaken with the permission of  
395 the Governor of the Province of Cebu and adhered to the Philippine ‘Wildlife Resources  
396 Conservation and Protection Act’.

397

398 **Data Availability**

399 The datasets generated and/or analysed during the study are available from the corresponding  
400 author on reasonable request.

649 **Table 1.** Comparisons between models of manta ray visits with single term deletions. “ELPD  
650 Difference” refers to the computed differences in the model’s ELPD values (each model compared  
651 to the model described in row 1), and SE difference is the estimated standard error of the  
652 difference.

653

---

	ELPD Difference	SE Difference
Day of Year + Minutes after High Tide + Minutes after 05:00 + Current Strength	0	0
- Minutes Observed	- 0.7	0.7
- Minutes After High Tide	- 0.9	0.5
- Temperature	- 1.1	0.2
- Current Strength	- 2.1	0.8
- Minutes After 05:00	- 8.6	4.2
- Day of the Year	- 15.3	5.5

Dorsal Head	0.1	0.4	-0.7912	0.7986
Tail	0.0	0.4	-0.9323	0.9139
<i>Thalassoma lunare</i>	-1.1	0.1	-1.3472	0.1894

695

696 **Table 7.** The patch proportions and absolute number of cleaning interactions recorded in each  
 697 patch for each cleaner fish species.

698

Patch	Patch Proportion	Interactions from <i>L. dimidiatus</i>	Interactions from <i>T. lunare</i>
Ventral Body	0.186	13	0
Pectorals	0.218	51	22
Gills	0.068	115	89
Ventral Head	0.037	4	7
Dorsal Lower	0.415	12	25
Pelvis	0.012	24	19
Dorsal Head	0.036	5	3
Tail	0.029	2	3
<i>Total</i>	<i>1.00</i>	<i>226</i>	<i>168</i>

699 **Figure Captions**

700

701 **Fig. 1.** The food patches onto which locations of cleaning interactions were mapped during the  
702 analysis of the video recordings.

703

704 **Fig. 2.** Manta ray visits to Monad Shoal, and general additive model fits for each of the  
705 explanatory variables **(a)** Day of the year **(b)** Time Observed **(c)** Current Strength (m / s) **(d)**  
706 Minutes after High Tide **(e)** Minutes After 05:00. Dots represent the presence and absence of giant  
707 manta rays with predicted probabilities on the y axis. Lines represent posterior means and shading  
708 around the lines indicates 95% credible bands.

709

710 **Fig. 3.** The rate of cleaning interactions compared between **(a)** Minutes After 05:00 **(b)** Manta ray  
711 identification term (boxplots summarize the posterior distributions) **(c)** Minutes After High Tide  
712 **(d)** Current Strength (m / s) **(e)** Temperature and **(f)** Day of the Year. The solid lines represent the  
713 posterior mean predictions with shading denoting the 95% credible bands.

714

715 **Fig. 4.** The effects of patch on the rate of cleaning interactions for *L. dimidiatus* (black), and *T.*  
716 *lunare* (grey). Effects are expressed relative to the dorsal head patch (dashed line) after controlling  
717 for patch area. Dots are posterior means, vertical bars are 95% credible intervals, and preference  
718 is expressed if they do not overlap. The parameter for ventral body, *T. lunare*, has been omitted  
719 since it could not be estimated from the data.
