We describe initial results by the Lattice Strong Dynamics (LSD) collaboration of a study into the variation of chiral properties of $SU(3)$ Yang-Mills gauge theory as the number of massless flavors changes from $N_f = 2$ to $N_f = 6$, with a focus on the use of chiral perturbation theory.

6th International Workshop on Chiral Dynamics

July 6-10 2009

Bern, Switzerland

*Speaker.

1. Motivation

Theories different from QCD have seen a considerable amount of recent attention from the lattice gauge theory community. In particular, the properties of $SU(N_c)$ Yang-Mills gauge theories with N_f light fermions have been the subject of numerous recent lattice studies [1, 2, 3, 4, 5] in the context of searching for novel non-perturbative physics which could play a role in building strongly-coupled models of physics beyond the standard model, e.g. technicolor. We will consider here only the case $N_c = 3$, with N_f fermions in the fundamental representation of the gauge group.

The infrared dynamics within this class of theories is known to undergo a transition as N_f is varied within the range $0 < N_f < N_f^{af}$ for which asymptotic freedom is preserved. It is well known that for N_f just below N_f^{af} , the β -function of the theory shows a weak infrared (IR) fixed point [6, 7], leading to conformal behavior in the IR. This is markedly different from the confining IR behavior of a QCD-like theory (small N_f); we expect a phase transition at some point as N_f is varied between the two extremes. Thus far, lattice studies have supported the picture that there is a ‘‘conformal window’’ $N_f^c < N_f < N_f^{af}$, with the fixed-point coupling strength becoming strong as N_f approaches the critical transition value N_f^c .

Lattice simulations are necessarily performed at finite fermion mass m_f , and must then be extrapolated to the physical point or the chiral limit. Thus, chiral perturbation theory (χ PT) is an invaluable tool in connecting our simulation results at various N_f with continuum physics. Although most interest thus far has been on $SU(2)$ and $SU(3)$ χ PT for application to QCD, generalization of χ PT to the breaking of an $SU(N_f) \times SU(N_f)$ chiral symmetry is quite straightforward, with the N_f counting factors well-known up to next-to-leading order (NLO). However, the values of the low-energy constants appearing in the chiral Lagrangian are not identical between the $SU(2)$ and $SU(N_f)$.

Of particular interest is the magnitude of the fermion condensate $\langle \bar{\psi}\psi \rangle$ relative to the Goldstone decay constant F , encapsulated in the ratio $\langle \bar{\psi}\psi \rangle / F^3$. In extended technicolor models, there is significant tension between the requirements of evading experimental bounds on flavor-changing neutral currents (requiring a large ultraviolet cutoff Λ_{ETC}), and generating standard-model quark masses which go as $\langle \bar{\psi}\psi \rangle_{TC} / \Lambda_{ETC}^2$, where $\langle \bar{\psi}\psi \rangle_{TC}$ is the technifermion condensate cut off at the scale Λ_{ETC} . A phenomenon known as ‘‘walking’’ can significantly enhance the ratio $\langle \bar{\psi}\psi \rangle / F^3$ relative to QCD [8, 9, 10], allowing generation of the correct masses without violating experimental bounds (see e.g. [11] for a brief review.) Continuum studies based on Feynman graphs have suggested just such a significant enhancement for theories with many flavors N_f , near (but just below) the transition value N_f^c [12, 13].

Determining the evolution of $\langle \bar{\psi}\psi \rangle / F^3$ is a primary goal of the Lattice Strong Dynamics (LSD) collaboration. Initial results were described in Ref. [14], comparing the well-known $N_f = 2$ theory to the case of $N_f = 6$, concluding that there is significant enhancement at $N_f = 6$. In this supplement to Ref. [14], to appear in the Proceedings of 6th International Workshop on Chiral Dynamics, we describe more completely the use of χ PT and the extrapolation to $m = 0$, with particular focus on the difficulties that arise at $N_f = 6$.

In section 2, we review the χ PT formulas for general N_f . In section 3, we detail our simulation methods and parameters. In section 4, we perform a variety of chiral fits to our data at both $N_f = 2$

and $N_f = 6$, with comparison between the two cases. In section 5, we make some concluding remarks.

2. χ PT at general N_f

The application of χ PT to theories with a general number of light fermion flavors N_f (all with mass m) is straightforward. Aside from the unknown N_f dependence of the low-energy constants themselves, N_f appears as a loop counting factor in NLO formulas and beyond. The general formulas at NLO for M_m^2 , F_m and $\langle \bar{\psi}\psi \rangle_m$ are [15]:

$$\frac{M_m^2}{2m} = B \left\{ 1 + \frac{2mB}{(4\pi F)^2} \left[2\alpha_8 - \alpha_5 + N_f(2\alpha_6 - \alpha_4) + \frac{1}{N_f} \log \left(\frac{2mB}{(4\pi F)^2} \right) \right] \right\} \quad (2.1)$$

$$F_m = F \left\{ 1 + \frac{2mB}{(4\pi F)^2} \left[\frac{1}{2}(\alpha_5 + N_f\alpha_4) - \frac{N_f}{2} \log \left(\frac{2mB}{(4\pi F)^2} \right) \right] \right\} \quad (2.2)$$

$$\langle \bar{\psi}\psi \rangle_m = F^2 B \left\{ 1 + \frac{2mB}{(4\pi F)^2} \left[\frac{1}{2}(2\alpha_8 + \eta_2) + 2N_f\alpha_6 - \frac{N_f^2 - 1}{N_f} \log \left(\frac{2mB}{(4\pi F)^2} \right) \right] \right\} \quad (2.3)$$

where $\alpha_i \equiv 8(4\pi)^2 L_i$ and $\eta_i \equiv 8(4\pi)^2 H_i$ are just the conventional low- and high-energy constants of χ PT, rescaled to values of $O(1)$. Both the analytic terms and the chiral logarithms scale with the number of fermions N_f ; except for the log correction to M_m^2 , the size of the NLO terms increases relative to the leading order as N_f increases. The lone high-energy constant η_2 which appears in $\langle \bar{\psi}\psi \rangle_m$ includes a ‘‘contact term’’, a quadratic divergence in the ultraviolet cutoff (here $1/a$, where a is the lattice spacing). We therefore expect the analytic term linear in m to dominate the chiral expansion of $\langle \bar{\psi}\psi \rangle_m$.

Without fitting to additional observables or resorting to partial quenching, we cannot distinguish the individual low- and high-energy constants in eqs. (2.1)–(2.3) above. Therefore in our analysis, we adopt a simpler notation by combining many of the coefficients:

$$\frac{M_m^2}{2m} = 8\pi^2 F^2 z \left\{ 1 + zm \left[\alpha_M + \frac{1}{N_f} \log(zm) \right] \right\} \quad (2.4)$$

$$F_m = F \left\{ 1 + zm \left[\alpha_F - \frac{N_f}{2} \log(zm) \right] \right\} \quad (2.5)$$

$$\langle \bar{\psi}\psi \rangle_m = 8\pi^2 F^4 z \left\{ 1 + zm \left[\alpha_C - \frac{N_f^2 - 1}{N_f} \log(zm) \right] \right\}, \quad (2.6)$$

where we have also defined the parameter

$$z \equiv \frac{2B}{(4\pi F)^2}. \quad (2.7)$$

The quantity zm is the expansion parameter of χ PT, so that $1/z$ gives a rough estimate of the mass scale at which we expect perturbation theory to break down.

At next-to-next-to-leading order (NNLO), six additional coefficients appear, corresponding to the m^2 and $m^2 \log m$ terms in the chiral expansion. The coefficients of the leading non-analytic terms $m^2(\log m)^2$, like the $m \log m$ terms above, are completely determined by N_f ; however, the

values of these coefficients for general N_f are not presently available, although they are known to alternate in sign from the NLO leading logarithmic terms. In investigating χ PT at NNLO in this paper, we will fix the coefficients of the $m^2(\log m)^2$ terms to unity (with the appropriate sign), as we do not have enough data to leave these coefficients arbitrary. Another possibility would be to use N_f times the $m \log m$ coefficients rather than unity, capturing the expected leading scaling with N_f ; however, this is likely to overestimate the effects of the $m^2(\log m)^2$ terms, just as setting the coefficients to 1 most likely leads to underestimation. In either case, the qualitative results reported below are the same.

Extending the notation of eqs. (2.1)–(2.3), we write

$$\frac{M_m^2}{2m} = 8\pi^2 F^2 z \left\{ 1 + zm \left[\alpha_M + \frac{1}{N_f} \log(zm) \right] + (zm)^2 \left[\alpha_{M20} + \alpha_{M21} \log(zm) - (\log(zm))^2 \right] \right\} \quad (2.8)$$

$$F_m = F \left\{ 1 + zm \left[\alpha_F - \frac{N_f}{2} \log(zm) \right] + (zm)^2 \left[\alpha_{F20} + \alpha_{F21} \log(zm) + (\log(zm))^2 \right] \right\} \quad (2.9)$$

$$\langle \bar{\psi} \psi \rangle_m = 8\pi^2 F^4 z \left\{ 1 + zm \left[\alpha_C - \frac{N_f^2 - 1}{N_f} \log(zm) \right] + (zm)^2 \left[\alpha_{C20} + \alpha_{C21} \log(zm) + (\log(zm))^2 \right] \right\}. \quad (2.10)$$

3. Simulation details

The study of unexplored aspects of chiral dynamics is a difficult proposition on the lattice, as lattice fermion discretization typically breaks chiral symmetry explicitly. For this study, we employ domain wall fermions [16, 17], which have good flavor symmetry properties and break chiral symmetry only by an exponentially small factor. In addition to the domain wall fermion action, we use the Iwasaki improved gauge action [18].

Gauge configurations are generated using the CPS application package, part of the USQCD software library. Evolution in configuration space is performed via the hybrid Monte Carlo (HMC) method, optimized with a three-level symplectic integrator, a single level of Hasenbusch preconditioning, and chronological inversion.

The lattice volume is set to $32^3 \times 64$. For the length of the fifth dimension we take $L_s = 16$, and the domain-wall height is set to $m_0 = 1.8$. Input fermion masses are varied from $m_f = 0.005$ to 0.03. Raw data are blocked over sets of 50 trajectories before analysis, in order to reduce the effects of autocorrelations; our runs are not long enough to perform a complete analysis of autocorrelation times.

Since we do not extrapolate $L_s \rightarrow \infty$, there is some residual chiral symmetry violation, which can be encapsulated in a residual mass m_{res} . The magnitude of the residual mass in the chiral limit is $m_{res} = 2.60 \times 10^{-5}$ in the $N_f = 2$ theory, and $m_{res} = 8.23 \times 10^{-4}$ for $N_f = 6$. To take the chiral limit, we extrapolate in the total fermion mass $m \equiv m_f + m_{res}$. The variation of m_{res} over the range of m_f used is extremely small compared to m , and we neglect it here.

In order to obtain a correct sampling of the partition function in finite volume, evolution of global topological charge Q is important. Our lightest evolutions at $m_f = 0.005$ show signs of very slow evolution in topological charge, which can lead to significant systematic shifts, particularly

in $\langle\bar{\psi}\psi\rangle_m$ and F_m [19]. Due to this unknown systematic effect, we exclude the $m_f = 0.005$ results wherever possible below, and caution that any fits which do contain data at this mass point are questionable.

4. Chiral extrapolation

We will consider an assortment of chiral fits, at both NLO and NNLO, varying both N_f and the mass ranges included in the fit. The set of fits to be considered is detailed in Table 1. Resulting best-fit parameters are shown in Table 2.

We begin at $N_f = 2$ with fit type A, which is simply an NLO fit to all of the available data (excluding $m_f = 0.005$, for the reasons given above.) The $\chi^2/\text{d.o.f.}$ is 6.5 with 4 degrees of freedom; given that our error bars are most likely underestimated due to the relatively small number of trajectories gathered, this indicates a reasonably good fit to the data. From Table 2 we note that α_M and α_F are $O(1)$ numbers, while α_C is very large so that the linear term dominates the $\langle\bar{\psi}\psi\rangle_m$ extrapolation, as expected from the presence of the ‘‘contact term’’. We expect the breakdown of chiral perturbation theory for $zm \approx 1$; since $1/z = 0.036$, the expansion should be good over the fit range used.

Despite our concerns about the $m_f = 0.005$ data, a natural question at this point is whether the NLO fit can be extended to include them. We attempt fit type B in order to investigate. The $\chi^2/\text{d.o.f.}$ rises significantly to 36.2, now with 7 degrees of freedom. The inability to incorporate these lighter-mass points into the original chiral fit is most likely due to the presence of large systematic errors in the data which are not reflected in the error bars, as we anticipated.

Attempting the same basic NLO fit (type A) at $N_f = 6$ is the logical next step, but unfortunately, the data does not support such a fit. As shown in Table 2, the values of the best-fit parameters are fairly close to those from the $N_f = 2$ fit, but the $\chi^2/\text{d.o.f.}$ is now 50.5, indicating a very poor fit to the data. Both fits of type A are plotted in Figure 1, and the poor quality of the $N_f = 6$ fit is immediately obvious. There is clear tension in the fit between the intercept values F and B expected from more naive extrapolation of the data, and the magnitude of the NLO terms governed by $z \propto B/F^2$. Including the $m_f = 0.005$ data (type B) does not improve the situation, with roughly the same best-fit parameters and a somewhat larger $\chi^2/\text{d.o.f.}$.

Fit label	Order	m_f range (M_m^2)	m_f range (F_m)	m_f range ($\langle\bar{\psi}\psi\rangle_m$)	N_{dof}
A	NLO	0.01-0.02	0.01-0.02	0.01-0.02	4
B	NLO	0.005-0.02	0.005-0.02	0.005-0.02	7
C	NLO	0.01-0.02	0.01	0.01	0
D	NNLO	0.005-0.02	0.005-0.02	0.005-0.02	1
E	NNLO	0.01-0.03	0.01-0.03	0.01-0.03	4

Table 1: Types of chiral fit considered. Both the order of the fit and mass ranges of data included for M_m^2 , F_m and $\langle\bar{\psi}\psi\rangle_m$ data are varied. Fits A through E are performed for both $N_f = 2$ and $N_f = 6$; fit F can be performed only at $N_f = 6$, where data at $m_f = 0.025, 0.030$ are available.

Figure 1: Chiral extrapolation of the quantities $M_m^2/2m$ and F_m , with χ PT fits of type A. Data points used in deriving the fits shown are dark red squares ($N_f = 2$) and dark blue triangles ($N_f = 6$); data excluded from the fit are lightly shaded. Best-fit results with 1- σ error bands are shown in corresponding colors.

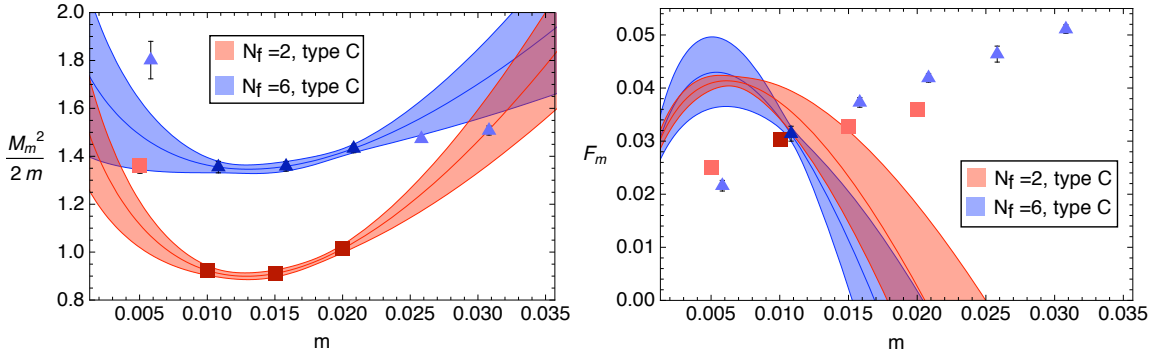

Figure 2: Chiral extrapolation of the quantities $M_m^2/2m$ and F_m , with χ PT fits of type C at both $N_f = 2$ (red) and 6 (blue). Data symbols and colors are as in Figure 1.

The failure of NLO χ PT at $N_f = 6$, over the same range of m_f which yielded a good fit at $N_f = 2$, is not entirely surprising in retrospect. Most of the NLO terms in eqs. (2.1)–(2.3) scale linearly with N_f , so that if we keep z fixed, then as we go from $N_f = 2$ to 6, we expect to have to work in a mass range which is a factor of 3 smaller to keep the size of the NLO terms fixed relative to LO.

An exception is the slope of the Goldstone mass squared, eq. (2.1). There, the chiral log is actually suppressed by $1/N_f$ (although there is still a linear increase with N_f buried in the linear coefficient α_M .) Indeed, by inspection the variation of $M_m^2/2m$ over the mass range $0.01 \leq m_f \leq 0.02$ is quite small, both at $N_f = 2$ and $N_f = 6$. We might therefore expect that a chiral fit to just the Goldstone mass data might be more successful. This is fit type C, which includes the range of M_m^2 data $0.01 \leq m_f \leq 0.02$, along with the lightest data point $m_f = 0.01$ for both F_m and $\langle \bar{\psi}\psi \rangle_m$ in order to fix α_F and α_C . We have zero degrees of freedom, so evaluation of goodness of fit is difficult.

Results for fits of type C are shown in Figure 2. Both fits of type C lead to a large value of the parameter z , pointing to an early breakdown of the chiral expansion; in both cases, the NLO

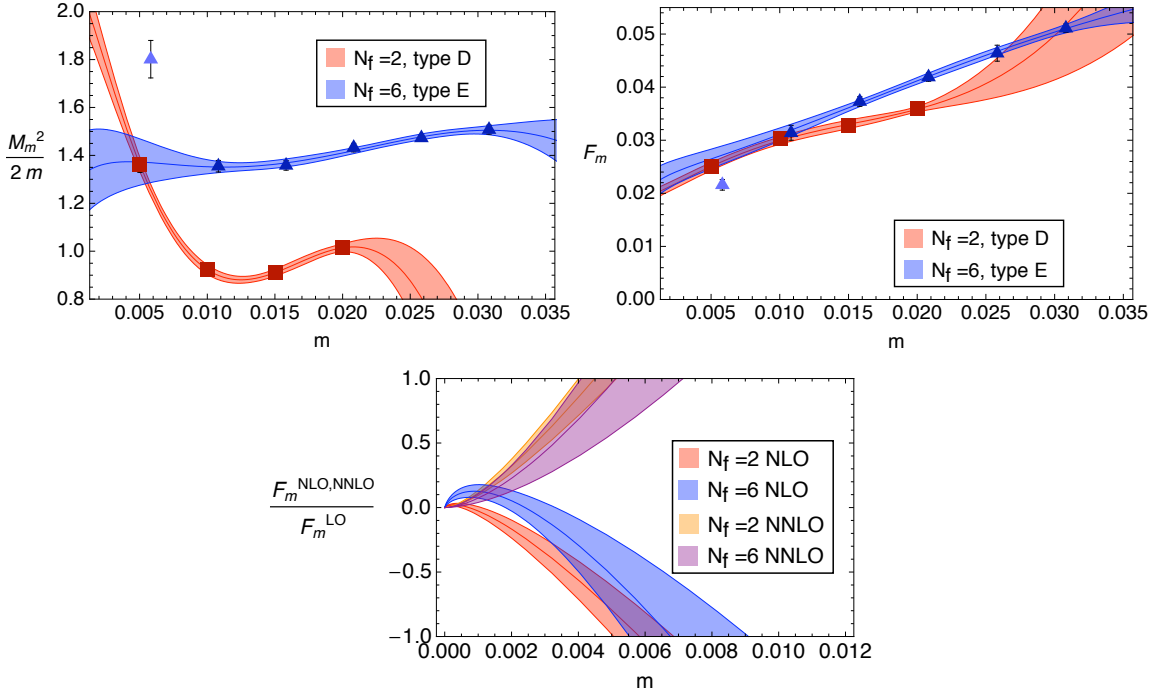

Figure 3: NNLO chiral extrapolation of the quantities $M_m^2/2m$ and F_m , with fits of type D at $N_f = 2$ and type E at $N_f = 6$. Data symbols and colors are as in Figure 1. The ratios of NLO and NNLO terms to LO in the F_m extrapolation are also displayed, showing that both terms become quite large relative to LO at the bottom of the mass range used.

terms in F_m are clearly large compared to the leading-order value at quite small m , with fine-tuned cancellation of the NLO terms occurring in order to match the single F_m point contained in the fits. Although we have no $\chi^2/\text{d.o.f.}$, the type C fit curves clearly do not match the F_m data except at the point $m_f = 0.010$ included in the fit.

Finally, we attempt the NNLO-inspired fits of eqs. (2.8)–(2.10). There are 11 fit parameters, so that we must include the $m_f = 0.005$ data at $N_f = 2$ (fit type D.) At $N_f = 6$, we can use the range $0.01 \leq m_f \leq 0.03$ (fit type E), which we might expect to yield a better result due to the systematic effects in the $m_f = 0.005$ data. Results are plotted in Figure 3. Although the fit to the data is good at first glance, with $\chi^2/\text{d.o.f.} < 1$ in all cases, separating out the NLO and NNLO terms relative to the leading order shows that both terms are $O(1)$ or larger at the bottom of the mass range being fit to (Figure 3). The apparent goodness of fit is inconsistent with a convergent chiral expansion, and instead is the consequence of delicate cancellations between the many terms available in order to fit the data.

5. Conclusion

Based on initial results from the LSD collaboration, we conclude that NLO χ PT gives a self-consistent fit to our $N_f = 2$ data, but does not yield a satisfactory fit to the data at $N_f = 6$ for our current mass range $0.01 \leq m_f \leq 0.02$. Alternative fit ranges and the inclusion of NNLO terms also

fail to give an acceptable $N_f = 6$ fit. As noted above, due to the linear scaling with N_f of several terms we might expect that at lighter mass points (by a factor of 3) will be necessary in going from $N_f = 2$ to $N_f = 6$. The inclusion of known finite-volume and finite-topology terms [19] in the chiral fits should allow us to fit to lighter masses without systematic errors and without greatly increasing the computational cost. Also, a true NNLO fit may allow a chiral fit from slightly heavier masses, once the computation of the leading double-log coefficients at NNLO for general N_f is carried out, although the sheer number of NNLO parameters will probably require simulation at additional masses in order to carry out such a fit successfully.

Alternative approaches, including partially quenched analysis or the use of eigenvalue methods, may provide another way forward for the extraction of chiral quantities at large N_f , and will be explored by our collaboration in future studies. Detailed analysis of the chiral extrapolation for the quantity $\langle \bar{\psi}\psi \rangle / F^3$ and of the physical implications of our results are carried out in [14].
