Abstract

Motivation: Recent progress in m⁷G RNA methylation studies has focused on its internal (rather than capped) presence within mRNAs. Tens of thousands of internal mRNA m⁷G sites have been identified within mammalian transcriptomes, and a single resource to best share, annotate and analyze the massive m⁷G data generated recently is sorely needed.

Results: We report here m7GHub, a comprehensive online platform for deciphering the location, regulation and pathogenesis of internal mRNA N7-methylguanosine. The m7GHub consists of four main components, including: the first internal mRNA m⁷G database containing 44,058 experimentally-validated internal mRNA m⁷G sites, a sequence-based high-accuracy predictor, the first web server for assessing the impact of mutations on m⁷G status, and the first database recording 1,218 disease-associated genetic mutations that may function through regulation of m⁷G methylation. Together, m7GHub will serve as a useful resource for research on internal mRNA m⁷G modification.

Availability: m7GHub is freely accessible online at: www.xjtlu.edu.cn/biologicalsciences/m7ghub.

1 Introduction

Over 150 different RNA modifications have been identified in all three kingdoms of life, playing important roles in various cellular processes (Jaffrey, 2014; Zaccara, et al., 2019). Among them, N7-methylguanosine (m⁷G), the most ubiquitous RNA cap modification, is added to the 5' cap co-transcriptionally during the initial phases of transcription and before other RNA processing events (Cowling, 2009). As a positively charged RNA modification, m⁷G capping plays significant roles in gene expression, protein synthesis, and transcript stabilization (Furuichi, et al., 1977). It has been found that almost every phase of the life cycle of mRNA can be regulated by m⁷G cap modification, including transcription (Pei and Shuman, 2002), mRNA splicing (Konarska, et al., 1984), nuclear export (Lewis and Izaurralde, 1997), and translation (Muthukrishnan, et al., 1975). The m⁷G RNA modification was also found in tRNA (Guy and Phizicky, 2014) and rRNA (Sloan, et al., 2017), where its presence has been associated with various diseases. For example, mutations in the METTL1-WDR4 may cause a distinct form of microcephalic primordial dwarfism (Shaheen, et al., 2015).

Thanks to the advances of high-throughput sequencing approaches developed for transcriptome-wide mapping of internal m⁷G modification (Chu, et al., 2018; Enroth, et al., 2019; Malbec, et al., 2019; Marchand,

et al., 2018; Zhang, et al., 2019), recent studies confirmed the widespread internal existence of m⁷G RNA modification on mRNAs, and revealed its conservation (Malbec, et al., 2019), regulation and dynamics (Zhang, et al., 2019) as well as its role in translation control. Zhang et al. invented the m⁷G-MeRIP-Seq and m⁷G-Seq techniques based on antibody immunoprecipitation and termination of reverse transcription, respectively (Zhang, et al., 2019). While m⁷G-MeRIP-Seq (Zhang, et al., 2019) provides only limited resolution (~100bp), m⁷G-Seq (Zhang, et al., 2019) achieved base-resolution in the detection of internal mRNA m⁷G sites by taking advantage of the misincorporation at m⁷G sites during reverse transcription. In addition, an alternative approach m⁷G-miCLIP-seq (Malbec, et al., 2019) was also developed by combining anti-m⁷G antibody immunoprecipitation enrichment with ultraviolet (UV) cross-linking. It provided an improved resolution (~30bp) than the conventional MeRIP-Seq method, and its resolution may be further narrowed down to base-resolution if combined with motif analysis.

Experimental methods are usually effective but still costly and laborious. To ensure that the massive data related to internal mRNA m⁷G methylation generated from high-throughput experiments are properly shared, annotated and taken advantage of, it is often beneficial to develop complementary bioinformatics solutions. To date, many in silico efforts have been made to support the study of the epitranscriptome or RNA epigenetics (Chen, et al., 2017; Chen, et al., 2019). For example,

the experimentally validated m⁶A and other RNA modification sites in different species were collected in RMBase and MetDB (Liu, et al., 2017; Xuan, et al., 2017) along with various functional annotations such as the splicing sites, microRNA targets and RNA protein binding sites. The RNA modification pathways can be queried from MODOMICS (Boccalletto, et al., 2017). Dedicated software tools and pipelines were developed for high-throughput sequencing data profiling various RNA modification marks (Cui, et al., 2016; Hauenschild, et al., 2015; Meng, et al., 2013; Rieder, et al., 2016; Schmidt, et al., 2019; Zhang, et al., 2019), and machine learning approaches such as iRNA-Methyl (Chen, et al., 2015), iRNA-m7G (Chen, et al., 2019), BERMP (Huang, et al., 2018), SRAMP (Zhou, et al., 2016), DeepPromise (Chen, et al., 2019), Gene2Vec (Zou, et al., 2018) and WHISTLE (Chen, et al., 2019) were designed for accurate prediction of RNA modification sites. Enzyme-specific RNA modification site predictions were made possible for PSI (He, et al., 2018) and m6A (Song, et al., 2019). Annotations related to RNA modifications may be obtained with RNAmoD (Liu and Gregory, 2019), RCAS (Uyar, et al., 2017) and RNA framework (Incarnato, et al., 2018). Meanwhile, the disease and functional association of m6A RNA modification was revealed by m6AVar (Zheng, et al., 2017), m6ASNP (Jiang, et al., 2018), m6Acomet (Wu, et al., 2019), Deepm6A (Zhang, et al., 2019), DRUM (Tang, et al., 2019) and FunDMDeep-m6A (Zhang, et al., 2019) via disease-associated genetic variants or gene regulatory network and enrichment analysis. However, to the best of our knowledge, bioinformatics efforts for internal m⁷G RNA modification are still scarce. None of the existing bioinformatics databases collected the internal mRNA m⁷G sites, and their disease association has not been systematically inferred.

We present here **m7GHub**, a centralized online platform for deciphering the location, regulation and pathogenesis of internal mRNA m⁷G RNA methylation. The m7GHub consists of the following four major components:

- 1) **m7GDB**: a database for experimentally validated internal mRNA m⁷G sites annotated with the post-transcriptional regulations potentially affected.
- 2) **m7GFinder**: a web server for high-accuracy prediction of putative internal mRNA m⁷G sites from DNA sequences or human genome coordinates.
- 3) **m7GSNPer**: a web server for assessing the epitranscriptome impact of genetic mutations on internal m⁷G RNA methylation.
- 4) **m7GDiseaseDB**: a database for the disease-associated genetic variants that may lead to the gain or loss of an internal m⁷G site, with implications for disease pathogenesis involving m⁷G RNA methylation.

Together, m7GHub serves as a useful online resource for the studies of internal mRNA m⁷G modification.

2 Materials and Methods

Internal mRNA m⁷G sites collected in m7GDB (m⁷G database)

We collected a total 69,159 internal m⁷G sites reported from eight experiments in two independent studies (Malbec, et al., 2019; Zhang, et al., 2019). The data were generated using three different techniques (m⁷G-Seq, m⁷G-MeRIP-seq and m⁷G-miCLIP-Seq). In m⁷G-seq, a chemical reactivity can induce misincorporation at m⁷G sites during the process of reverse transcription, and all the known genomic mutation sites from dbSNP were excluded from the results to reveal m⁷G modification sites at base resolution. The same data processing protocol was implemented as the original publication (Zhang, et al., 2019) to reproduce the internal m⁷G map in HeLa and HepG2 cell lines, respectively, at base-resolution

level. For m⁷G-MeRIP-Seq (Zhang, et al., 2019) and m⁷G-miCLIP-Seq, all the guanines localized within the reported m⁷G peaks or clusters (of 30bp window) were collected. It is worth mentioning that, as m⁷G-MeRIP-Seq and m⁷G-miCLIP-Seq are not base-resolution approaches, the G sites extracted from the reported regions by the two techniques should still contain a large proportion of non-m⁷G sites. In m7GDB, the reliability of the m⁷G sites reported from these two techniques was further assessed using our customized m⁷G site predictor m7Gfinder (detailed in the following). The datasets collected in m7GDB are summarized in **Table 1**.

Table 1. Data collected in m7GDB

ID	Site #	Cell Line	Technique	Resolution	Dataset	Source
H1	6,032	HeLa	m ⁷ G-Seq	1bp	GEO: GSE112276	(Zhang, et al., 2019)
H2	3,333	HepG2				
H3	17,225	HeLa	m ⁷ G-MeRIP-Seq	~100bp		
H4	21,577	HepG2				
H5	18,956	HEK293T				
H6	517	HeLa	m ⁷ G-miCLIP-Seq	~30bp	GSA: CRA001302	(Malbec, et al., 2019)
H7	942	RppH-HEK293T				
H8	568	TAP-HEK293T				
Total	69,159 record (44,058 unique sites)					

Note: m7GDB collected 44,058 unique internal mRNA m⁷G sites reported by three different sequencing approaches under eight experiment conditions.

Internal small RNAs m⁷G sites collected in m7GDB (m⁷G database)

Besides the internal m⁷G sites on mRNAs, m7GDB also collected the known internal m⁷G sites on small RNAs (tRNA and rRNA) reported from m⁷G-MaP-Seq (Enroth, et al., 2019) and MODOMICS (Boccalletto, et al., 2018) (see **Supplementary Table S1**).

Training and testing data for m7Gfinder (m⁷G site predictor)

We developed a customized predictor, m7Gfinder, for internal m⁷G sites. The primary training and testing datasets were generated from the base-resolution m⁷G profiling technique m⁷G-Seq (Zhang, et al., 2019). Additionally, m7Gfinder is validated on two independent techniques (m⁷G-MeRIP-Seq and m⁷G-miCLIP-Seq). For those m⁷G peaks identified by m⁷G-MeRIP-Seq (Zhang, et al., 2019), all the guanines localized within the reported peak ranges were considered as positive sites in the validation. For m⁷G-miCLIP-Seq (Malbec, et al., 2019), we retained only the guanines located within both the reported 30bp flanking windows and the claimed m⁷G motifs AACAAG (Malbec, et al., 2019) for performance validation of m7Gfinder. To construct the m⁷G prediction model under the full transcript mode, the human m⁷G base-resolution sites from m⁷G-Seq were used as positive data, and the negative m⁷G sites were randomly collected from unmodified G sites located on the same transcripts as sites used as positive data. As the existing data overwhelmingly relies on polyA selection, it cannot effectively capture intronic RNA fragments and may lead to an over-estimation in the predic-

tion accuracy under the full transcript mode, a mature mRNA mode was also considered as previously described (Chen, et al., 2019). Under the mature mRNA mode, the positive and negative m⁷G sites were filtered so that only those located on mature mRNAs remained (see **Supplementary Fig. S1**).

It is worth noting that the full transcript and mature mRNA modes were considered here are different from those implemented in the SRAMP method (Zhou, et al., 2016). In the SRAMP method, the two models (full transcript and mature mRNA) describe whether predictive features should be extracted from pre-mRNA or mature mRNA; while in our method, the two models describe whether intronic sites were considered in the training and evaluation process. Due to the polyA selection step in RNA-seq library construction, intronic signals are likely to be under-represented in experiment data, leading to an over-estimation in performance evaluation under full transcript mode when intronic sites were considered; A mature mRNA mode is thus proposed for more accurate performance evaluation.

For optimal use of the limited number of experimentally validated internal mRNA m⁷G sites, we collected 10 negative sites for each positive one, and the negative sites were randomly split into 10 subsets to generate 10 separate predictors each with 1:1 positive-to-negative ratio. The same procedure was also applied to generate negative sites for testing data, and the prediction results of the 10 predictors were averaged. For datasets generated from base-resolution technique (H1 and H2), dataset level cross-validation was performed, in which one of the datasets was used as training purpose, while the other one was used for independent testing. Furthermore, the H3-H8 datasets generated from m⁷G-MeRIP-Seq and m⁷G-miCLIP-Seq were also used for performance validation.

Predictive features of m7GFinder

To achieve the best possible predictive performance, the m⁷G site predictor we constructed considered both sequence and genome-derived features as previously described in similar work (Chen, et al., 2019; Chen, et al., 2017).

Sequence-derived features. The sequence-based features centered on m⁷G and non-m⁷G sites within the 41 bp flanking window were encoded by the chemical properties of nucleotides and nucleotide density. The chemical properties of the four types of nucleotides (A, G, C and U) were classified into three categories. The first category focused on the difference of the ring structure, in which adenosine and guanosine have two rings, while cytidine and uridine have one ring; In the second category, hydrogen bonding is considered, in which guanosine and cytidine can form one more hydrogen bond than adenosine and uridine. In the last category, distinction is made in which adenosine and cytidine contain the amino group, whereas it is the keto group in the case of guanosine and uridine. To sum up, a vector $S_i = (x_i, y_i, z_i)$ can represent the i -th nucleotide from the sequence:

$$x_i = \begin{cases} 1 & \text{if } s_i \in \{A, G\} \\ 0 & \text{if } s_i \in \{C, U\} \end{cases}, y_i = \begin{cases} 1 & \text{if } s_i \in \{A, C\} \\ 0 & \text{if } s_i \in \{G, U\} \end{cases}, z_i = \begin{cases} 1 & \text{if } s_i \in \{A, U\} \\ 0 & \text{if } s_i \in \{C, G\} \end{cases} \quad (1)$$

Therefore, the A, C, G, U can be encoded as a vector including three features (1,1,1), (0,1,0), (1,0,0) and (0,0,1), respectively. Additionally, the cumulative nucleotide frequency of nucleotide in the i -th position is calculated for the nucleotide density. To define the density of nucleotide in i -th position, the formula $d_i = A_i / i$ is introduced as the sum of the occurrences of the nucleotide A_i before the $i+1$ position divided by its position i . If we use a sample sequence 'CGGAUAC' to explain the formula, the cumulative frequency for adenosine at the fourth and sixth position is calculated as 0.25 (1/4) and 0.33 (2/6), respectively; similarly,

the frequency for cytidine is 1 (1/1) and 0.29 (2/7) at the first and seventh position of the sample sequence.

Genome-derived features. Besides the conventional sequence-derived features mentioned above, we also integrated 42 additional genome-derived features (**Supplementary Table S2**) into our m⁷G site prediction model that may contribute to the prediction accuracy, including 35 features considered previously (Chen, et al., 2019) and 7 new features. Specifically, we first paid attention to the transcript regions within which the guanosine falls: this information was represented by the Genomic Features 1-16 as dummy variable features, as generated by the GenomicFeatures R/Bioconductor package using the transcript annotations hg19 TxDb package (Lawrence, et al., 2013). We only extracted the transcript sub-regions on the primary (longest) transcripts of each gene, helping to eliminate isoform ambiguity from our analysis. For Genomic Features 17-20, we considered the relative position of the transcript regions (3'UTR, 5'UTR, CDS, and whole transcript) as encoded by a real value, such as the distance from the guanosine to the 3' end divided by the width of the region. If a site does not belong to one specific region, the value is set to zero. The length of the transcript region where m⁷G modification sites fall was represented by Genomic Features 21-25. For Genomic Features 26-27, the distance from the guanosine sites to the 5' end or 3' end of the splicing junctions is considered. The Phast-Cons (Siepel, et al., 2005) score and the fitness consequence (Gulko, et al., 2015) scores are used to measure the conservation degree, which are shown in features 28-31 calculated for the guanosine sites and its flanking regions. The RNA secondary structures around the guanosine site are predicted using RNAfold from the Vienna RNA package (Lorenz, et al., 2011) and shown in features 32-33. Genomic properties of transcripts where m⁷G sites are located were represented in features 34-38. Last but not least, the attributes of genes or transcripts were represented in features 39-42, such as microRNA targeted genes (Chou, et al., 2017) and HNRNPC binding sites (2012). Please refer to **Supplementary Table S2** for the details of all the 42 genomic features considered in m7GFinder.

Machine learning approach and performance evaluation of m7GFinder

SVM (Support Vector Machine) has been shown to be a quite effective machine learning algorithm in the field of computation biology and achieved good performance previously in prediction of m⁶A RNA methylation sites (Chen, et al., 2017). We applied the R language interface of LIBSVM (Chang and Lin, 2011) to construct our m⁷G site prediction model, and the radial basis function was set as kernel following the default setting for other parameters. A 5-fold cross-validation was performed on training dataset, and the final performance of the m7GFinder was evaluated by independent testing datasets including those generated from the same or different techniques, as described previously. The prediction accuracy was represented by the ROC (receiver operating characteristic curve) (sensitivity against 1-specificity), and the area under ROC curve (AUROC) was calculated as the main performance evaluation metric. Only the m⁷G sites not previously applied to training data were considered in the performance testing, so that the performance directly reflects the capability of our approach in discovering less prominent (or condition-specific) previously unknown m⁷G sites, rather than well-established (or house-keeping) internal m⁷G sites that are robustly detected in different m⁷G profiling experiments, as previously implemented (Chen, et al., 2019).

When comparing the performances of m7GFinder and a previous developed m⁷G site predictor iRNA-m7G, since the iRNA-m7G web server reports only the putative m⁷G sites with scores above its cutoff level, we

cannot calculate the area under ROC curve (AUROC) as previously; instead, the sensitivity (Sn), specificity (Sp), accuracy (ACC), and Matthews correlation coefficient (MCC) were presented for performance evaluation, specifically:

$$Sn = \frac{TP}{TP + FN} \quad (2)$$

$$Sp = \frac{TN}{TN + FP} \quad (3)$$

$$MCC = \frac{TP \times TN - FP \times FN}{\sqrt{(TP + FP) \times (TP + FN) \times (TN + FP) \times (TN + FN)}} \quad (4)$$

$$ACC = \frac{TP + TN}{TP + TN + FP + FN} \quad (5)$$

where TP represents the true positive, while TN represents the true negative; FP is the number of false positive, and FN the number of false negative.

Output of m7GFinder

To convey whether a guanosine site is more likely to be an m⁷G RNA methylation site or not, the likelihood ratio (LR) is calculated as the formula below, and reported in m7GFinder as its output:

$$LR = \frac{P(\text{observation} | m^7G)}{P(\text{observation} | G)} \quad (6)$$

A larger LR value means that the site is more likely to be an m⁷G RNA methylation site. The upper bound of a p-value can be inferred from the LRs of all the transcriptome G sites. It suggests how extreme is the observed LR among all the transcriptome G sites, and can be used to assess the statistical significance of a LR value. This is also reported by m7GFinder.

Annotation of post-transcriptional regulations affected by internal mRNA m⁷G

To unveil the potential impact of m⁷G in post-transcriptional regulations, we found the intersection of all the internal m⁷G sites with RBP regions and miRNA targets. Notably, although the binding information of METTL1, a known m⁷G methyltransferase, is not available from existing RBP database. This information has been manually added to m7GHub (Bao, et al., 2018). Furthermore, we obtained the regions of splicing sites within 100 bp upstream and downstream, the m⁷G sites localized on this regions were also collected for analysis. These functional annotations are available in both m7GDB and m7GFinder (when the inputs are genome coordinates).

Assessment of the impact of genetic mutations on internal mRNA m⁷G methylation status by m7GSNPer

The web server m7GSNPer was designed to evaluate the epitranscriptome impact of genetic mutations on internal m⁷G RNA methylation status. A variant is defined as m⁷G-associated variant if it can cause the alteration of methylation status of an internal mRNA m⁷G site, including two scenarios: (1) a mutation directly alters G to another base, leading to the loss of an experimentally validated or computationally predicted m⁷G site, or alters another nucleotide to G, leading to the gain of a computationally predicted m⁷G site; (2) a mutation alters the nucleotide within the 41 bp flanking window of an experimentally validated or computationally predicted m⁷G site, causing significant increase or decrease in

the probability of m⁷G methylation, as is reported by our customized m⁷G site predictor m7GFinder.

The m⁷G sites considered in m7GSNPer were classified into three confidence levels. The high confidence level involves experimentally validated m⁷G sites reported by base-resolution sequencing approach m⁷G-seq. The medium level involves m⁷G sites identified from non-base-resolution approaches (m⁷G-MeRIP-Seq and m⁷G-miCLIP-Seq). In addition, m7GFinder was applied transcriptome-wide to identify all the putative m⁷G sites, which are defined as m⁷G sites of low confidence level. The complete dataset of 37,094,832 germline variants (dbSNP151) from dbSNP (Sherry, et al., 2001) and 3,820,716 somatic variants (TCGA v15.0) from TCGA (Tomczak, et al., 2015) were collected as inputs to decipher the applications of m⁷G SNP. Only the variants localized on exons were considered in the analysis.

Association analysis between m⁷G and various diseases (m7GDiseaseDB)

The m7GDiseaseDB was developed to explore the potential association between m⁷G sites and disease-associated genetic mutations, which might implicate possible disease pathogenesis involving m⁷G RNA methylation. In this analysis, the disease-associated variants act as a potential bridge to link m⁷G RNA modification to known diseases. In order to unveil the potential impact of m⁷G modification on diseases, disease-associated SNPs (tagSNPs) were derived from different resources, including GWAS catalog (Buniello, et al., 2018), Johnson and O'Donnel (Johnson and O'Donnell, 2009) and ClinVar (Landrum, et al., 2015), we then mapped all m⁷G-associated variants to the collected tagSNPs. To annotate m⁷G sites and m⁷G-associated variants, the transcript structure from UCSC (Lawrence, et al., 2013) was used, and the evolutionary conservation of sequence was extracted from phastCons 20-way (Siepel, et al., 2005). In addition, the deleterious level of each m⁷G-SNPs was analyzed by SIFT (Kumar, et al., 2009), PolyPhen2 HVAR (Adzhubei, et al., 2010), PolyPhen2HDIV (Adzhubei, et al., 2010), LRT (Chun and Fay, 2009) and FATHMM (Shihab, et al., 2013) using ANNOVAR package (Wang, et al., 2010).

Website construction

MySQL tables were exploited for the storage and management of the metadata in m7GHub. Hyper Text Markup Language (HTML), Cascading Style Sheets (CSS) and Hypertext Preprocessor (PHP) were used to construct the web interface. The multiple statistical diagrams were presented by EChars, and Jbrowse genome browser (Skinner, et al., 2009) was employed for interactive exploration and visualization of relevant genome coordinate-based records.

3 Results

Collection of internal mRNA m⁷G sites in m7GDB

A total of 44,058 internal m⁷G sites were collected from data generated under eight samples profiled with three different techniques in two independent studies (see **Table 1**). These sites were annotated with post-transcriptional regulations such as miRNA target sites, alternative splicing sites and RNA binding protein target sites, which may be potentially regulated by internal mRNA m⁷G methylation. The reliability of internal m⁷G sites extracted from non-base-resolution techniques was also re-evaluated using our customized m⁷G predictor m7GFinder. To the best of our knowledge, m7GDB is the first and only database for internal mRNA m⁷G sites. Besides, m7GDB also collected internal m⁷G sites detected in small RNAs, i.e., tRNA and rRNA, as well as the m⁷G sites collected in MODOMICS database (see **Supplementary Table S1**),

making m7GDB the most comprehensive collection of internal RNA m⁷G sites.

3.1 Feature selection, and performance evaluation of m7GFinder

For m⁷G site prediction, both full transcript mode and mature mRNA mode were constructed. The m⁷G-Seq introduced by Zhang et al. (Zhang, et al., 2019) performed polyA selection in the step of RNA-seq library preparation. Therefore, the mature mRNA mode was considered to reduce the potential over-estimation of accuracy. Feature selection was implemented to identify the most important subset of genomic features, which in return avoids the over-fitting issue. We implemented the Perturb method (Gevrey, et al., 2003) to evaluate the relative importance of each genomic feature under the two modes. The ranking of each genome-derived feature can be found in **Supplementary Fig. S2**. To achieve the most robust performance, we used the top 19 genomic features to construct the predictor under full transcript mode, and the top 22 for mature mRNA mode.

Table 2. Performance evaluation of m7GFinder (AUROC)

Mode	Testing Method	Encoding Method	Base-resolution technique (m ⁷ G-Seq)		
			Hela	Hep G2	Average
Full Transcript	Cross validation	m7GFinder	0.977	0.976	0.977
		PseKNC2	0.750	0.721	0.736
		EIIP	0.786	0.785	0.786
		PSNP	0.844	0.837	0.841
		Composition	0.785	0.783	0.784
		MethyRNA	0.824	0.772	0.798
		AutoCorrelation	0.700	0.640	0.670
	Independent Dataset	m7GFinder	0.973	0.974	0.974
		PseKNC2	0.697	0.705	0.701
		EIIP	0.737	0.783	0.760
		PSNP	0.808	0.811	0.810
		Composition	0.737	0.781	0.759
		MethyRNA	0.728	0.759	0.744
		AutoCorrelation	0.673	0.639	0.656

		PseKNC2	0.591	0.577	0.584
		EIIP	0.651	0.614	0.633
		PSNP	0.688	0.649	0.669
		Composition	0.649	0.613	0.631
		MethyRNA	0.730	0.718	0.724
		AutoCorrelation	0.520	0.511	0.516

Note: 93.9% of m⁷G sites reported by m⁷G-Seq can be identified by m7GFinder under full transcript mode (sensitivity: 0.939) at the cut-off of 0.5 in prediction probability.

The performance of the newly constructed m⁷G site predictor (m7GFinder) was evaluated by 5-fold cross validation, independent testing, and compared with other sequence-derived encoding methods, including PseKNC2 (Liu, et al., 2015; Liu, et al., 2015), EIIP (He, et al.,

2018; He, et al., 2019), PSNP (He, et al., 2018; He, et al., 2019), Composition (Zhou, et al., 2016), MethyRNA (Chen, et al., 2017) and AutoCorrelation (Liu, et al., 2015; Liu, et al., 2015) (see **Table 2**). When testing on independent datasets generated from two cell lines, m7GFinder achieved an average AUROC of 0.974 and 0.889 under full transcript and mature mRNA modes, respectively, which was superior to the other sequence encoding schemes as well as the newly developed iRNA-m7G method (AUROC of 0.946 under full transcript mode) (Chen, et al., 2019).

It was shown previously that technological preference may significantly affect the results of epitranscriptome profiling (Adachi, et al., 2018; Hussain, et al., 2013; Zaringhalam and Papavasiliou, 2016). As m7GFinder was trained on base-resolution m⁷G-seq data, and the performance can be significantly over-estimated under the full transcript mode, we further validated its performance on datasets generated from two other m⁷G profiling techniques (m⁷G-MeRIP-Seq and m⁷G-miCLIP-Seq) under mature mRNA mode. Consistent with previous results, the newly developed m7GFinder approach substantially outperformed other encoding schemes (**Supplementary Table S3**) on datasets generated by both m⁷G-MeRIP-Seq and m⁷G-miCLIP-Seq techniques, with AUROC = 0.753 and 0.855, respectively. Taken together, these results suggest that m7GFinder should be a reliable tool for identifying putative internal mRNA m⁷G sites. It is worth noting that, although different overall patterns of internal mRNA m⁷G sites were reported previously in m⁷G-miCLIP-Seq (showing enrichment of internal mRNA m⁷G in 5'UTRs) and m⁷G-seq (showing enrichment of m⁷G in 3'UTRs) (Malbec, et al., 2019; Zhang, et al., 2019), the prediction results of m⁷G-seq-trained predictor agreed well with the m⁷G-miCLIP-Seq data (AUROC = 0.855), suggesting that the positive sites captured by the two techniques share something significant in common, and that these features were successfully captured by our predictor m7GFinder. Meanwhile, as explained previously, m⁷G-MeRIP-Seq is not a base-resolution technique, and there exist a large number of unmodified G sites under the m⁷G peaks called from m⁷G-MeRIP-Seq data; nevertheless, the results of m7GFinder and m⁷G-MeRIP-Seq data were coherent (AUROC = 0.753), suggesting consistent patterns were captured among them.

In addition, we further compared the performance of m7GFinder with iRNA-m7G, which, to our knowledge, is so far the only computational model published for internal mRNA m⁷G site prediction. As the area under ROC curve (AUROC) cannot be calculated from the output of the iRNA-m7G web server of, we instead calculated the sensitivity (Sn), specificity (Sp), accuracy (ACC), and Matthews correlation coefficient (MCC) for performance evaluation. Meanwhile, since the training data used for iRNA-m7G was generated from m⁷G-seq, to avoid overfitting, we applied the dataset from another technique m⁷G-miCLIP-seq for an independent testing. As is shown in **Table 3**, our newly proposed model m7GFinder obtained the highest accuracy of 0.760, which is approximately 9.3% higher than that of iRNA-m7G method.

The performance evaluation of predictor on the binding regions of enzymes related to m⁶A RNA modification have been applied in previously study (Zhou, et al., 2016). In our study, we also tested whether the newly proposed approach can predict the binding sites of METTL1, which is a known m⁷G methyltransferase. The motifs inside the experimentally identified METTL1 binding regions (Bao, et al., 2018) were used as the positive data. While the negative sites were randomly selected outside the METTL1 binding region, keeping the 1:10 positive-to-negative ratio. Consistent with previous results, m7GFinder substantially outperformed other encoding schemes under mature mRNA model (see **Supplementary Table S4**), suggesting again the reliability of our method from a

different perspective. Besides, the comparison between different algorithms indicated that SVM (Support Vector Machine) was a quite effective machine learning approach and achieved the best performance in our study.

Table 3. Performance comparison of different methods tested on independent dataset generated by m⁷G-miCLIP-Seq

Encoding Method	m ⁷ G-miCLIP-Seq			
	Sn	Sp	ACC	MCC
m7GFinder	0.842	0.710	0.760	0.536
iRNA-m7G	0.866	0.469	0.667	0.364
PseKNC2	0.571	0.564	0.567	0.134
EIIP	0.634	0.620	0.626	0.253
PSNP	0.688	0.790	0.728	0.467
Composition	0.635	0.622	0.628	0.257
MethyRNA	0.684	0.664	0.673	0.347
AutoCorrelation	0.553	0.556	0.554	0.108

3.2 Assessing the impact of mutations on internal m⁷G methylation (m7GSNPer)

The m7GSNPer web server was developed to evaluate the impact of genetic variants on internal m⁷G RNA methylation based on both our customized high-accuracy m⁷G site predictor (m7GFinder) and the collection of experimentally validated internal mRNA m⁷G sites. It critically assesses the changes (in the probability) of m⁷G methylation induced by an arbitrary genetic mutation, unraveling the potential functional machinery of the mutation via the epitranscriptome regulation. The m7GSNPer server also systemically annotates the m⁷G-associated variants with disease analysis and various post-transcriptional regulations as with m7GDB. To our knowledge, it is the first of its kind developed for assessing the impact of mutations on internal m⁷G RNA modification.

3.3 Comparing the m⁷G and non-m⁷G associated variants (m7GDiseaseDB)

With m7GSNPer, we systematically evaluated the potential relationship between the methylation status of internal mRNA m⁷G sites and all the known genetic variants around it. In total, we found 57,769 m⁷G-associated SNPs, which may cause the gain or loss of an m⁷G site in human (see **Supplementary Table S5**). A total of 735 and 12,800 genetic variants may cause the loss of an experimentally validated m⁷G site at high and medium confidence level, respectively. We observed that the m⁷G-associated SNPs were enriched in coding DNA sequence (a total of 50,970 m⁷G-associated SNPs, 90.54%), and especially for the predicted level (40,275 SNPs, 92.75%). The distribution characteristics of m⁷G-associated SNPs and non-m⁷G SNPs in different transcript structures were summarized in **Supplementary Table S6**. We then asked that if m⁷G-associated variants differ from those non-m⁷G-associated variants (non-m⁷G variants) in some biological meaning ways. PhastCons score was considered to evaluate the conservation degree between the two categories of variants. We found that the m⁷G-associated variants were more conserved than non-m⁷G variants (see **Fig. 1A**), suggesting that the sites where m⁷G-associated variants localized may undergo stronger selection pressure than that of non-m⁷G variants, and the genetic mutations on those more conservative sites may relate to relatively more important biological functions (e.g., the change of m⁷G methylation). Besides, the m⁷G-associated variants were predicted to have a higher proportion in both high-deleterious (14,589 variants, 25.56%; P < 0.001,

Chi-squared test) and medium-deleterious (13,615 variants, 23.85%; P < 0.001, Chi-squared test) levels, compared with non-m⁷G variants (**Fig. 1B**). Moreover, the proportion of nonsynonymous variants in m⁷G-associated SNPs is higher than non-m⁷G SNPs (**Fig. 1C**, P < 0.001, 2-tailed population test), revealing the variants that affect m⁷G methylation were also more likely to alter the amino acids in a protein sequence. We also observed that m⁷G-associated SNPs occurred more frequently in binding regions of METTL1 than the non-m⁷G SNPs with a p-value smaller than 0.001 (**Supplementary Fig. S3**). To sum up, these results suggested that the m⁷G-associated variants can be distinguished from the majority of passenger variants, and may have important roles in human genomes.

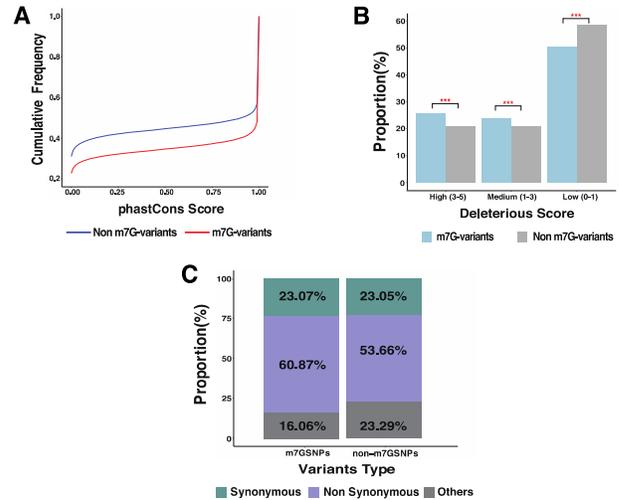

Fig. 1. The comparison between m⁷G-associated variants and non-m⁷G-associated variants. **A)** The cumulative distribution function of differences between phastCons score of m⁷G-associated variants and non-m⁷G variants, m⁷G-associated variants were more conservative than non-m⁷G variants. **B)** Proportional distribution of the m⁷G-associated variants and non-m⁷G variants at high, medium, and low deleterious levels. The deleterious level was analyzed by SIFT (Kumar, et al., 2009), PolyPhen2 HVAR (Adzhubei, et al., 2010), PolyPhen2HDIV (Adzhubei, et al., 2010), LRT (Chun and Fay, 2009) and FATHMM (Shihab, et al., 2013), a high level indicated that the variant was considered deleterious in at least 3 out of the 5 above-listed methods. **C)** Proportional distribution of the m⁷G-associated variants and non-m⁷G variants at different variant types, nonsynonymous type constitutes the majority of the m⁷G-associated variants.

3.4 Association of disease and internal mRNA m⁷G sites (m7GDiseaseDB)

The identified m⁷G-associated variants were also annotated with disease information and various post-transcriptional regulations (see **Supplementary Table S7**). For RBP binding regions, 6,863 and 22,078 m⁷G-associated variants from dbSNP and TCGA are related to 166 and 170 RBPs. For disease association analysis, 1,218 m⁷G variants localized on 716 genes were found to be associated with 681 diseases, which highlights the potential pathogenic role of the disease-related genetic mutations via the regulation of internal m⁷G RNA methylation functioning at the epitranscriptome layer.

We then identified the disease phenotypes that are most enriched with m⁷G variants. Among them, 33 variants (2.71%) were related to hereditary cancer-predisposing syndrome (ClinVar study, Accession: RCV000130572.2), followed by 16 variants (1.31%) relate to cardiovascular phenotype and 16 variants (1.31%) in primary ciliary dyskinesia (see **Table 4**).

In the previous disease-relevant studies, synonymous variants were often being neglected by their property of not altering the amino acids sequence of a protein. As more evidences have been found to support the

effects of synonymous variants on various diseases (Sauna and Kimchi-Sarfaty, 2011), m7GSNPer and m7GDiseaseDB were designed to classify the predicted variants into synonymous and nonsynonymous groups. Take rs158921 as an example, this synonymous variant alters guanine to adenine at position 60241142 of positive strand on chromosome 15, and is related to Cockayne syndrome (ClinVar study, accession: RCV000278856.1). We also observed an m⁷G methylation site at this position by m⁷G-Seq, and speculated that the dysregulation of m⁷G modification may relate to Cockayne syndrome. Together, the disease-relevant information provided in m7GDiseaseDB is particularly valuable for deciphering the disease mechanisms involving internal mRNA m⁷G methylation.

Table 4. Disease types most enriched with m⁷G variants

Name	#	Database	Study accession	Clinical significance	Identifiers
Hereditary cancer-predisposing syndrome	33	ClinVar study	RCV00013057 2.2	Uncertain significance	MedGen: C002767 2
Cardiovascular phenotype	16	ClinVar study	RCV00024937 7.1	Likely benign	MedGen: CN23073 6
Primary ciliary dyskinesia(PCD)	16	ClinVar study	RCV00046218 1.1	Benign	OMIM: PS24440 0

3.5 The m7GHub website

As a comprehensive online platform, m7GHub consists of four major components m7GDB, m7GFinder, m7GSNPer and m7GDiseaseDB, as previously described, to support studies related to internal mRNA m⁷G methylation in human (Fig. 2).

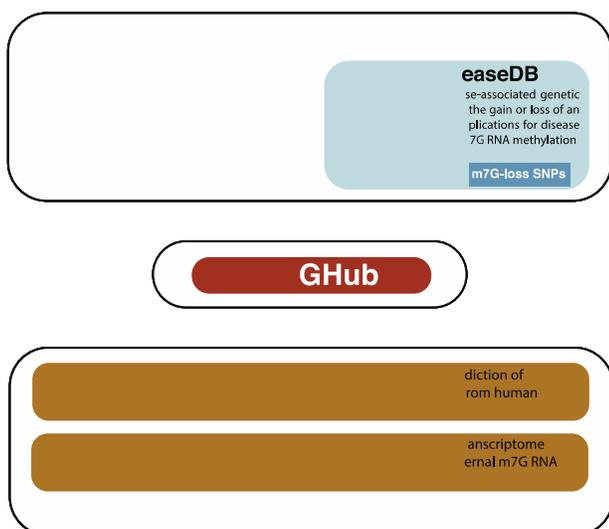

Fig. 2. The overall design of m7GHub. The m7GHub consists of m7GDB, m7GFinder, m7GSNPer and m7GDiseaseDB for deciphering the location, regulation and disease pathogenesis of internal mRNA m⁷G modification.

All the components of m7GHub can be easily accessed through the homepage of m7GHub (www.xjtlu.edu.cn/biologicalsciences/m7ghub) with simple and clear guidance (Fig. 3). In m7GDB, all the experimentally validated internal mRNA m⁷G sites are classified by their sequencing techniques (m⁷G-Seq, m⁷G-MeRIP-Seq, and m⁷G-miCLIP-Seq), together with the detailed annotation of potentially affected post-transcriptional regulations. m7GFinder accepts either FASTA format or a simply tab-delimited txt format containing genome coordinates as the input file, and returns as results a report of the identified putative m⁷G sites with statistical summary and a location map. For any particular genetic mutations that researchers may be interested in, the web server m7GSNPer enables the users to upload their genetic variant files for analysis. A comprehensive report containing the epitranscriptome impact of the mutations on m⁷G RNA methylation with disease relevance annotations will be returned together with the statistical summary and explanation of each returned results for the users to explore. For m7GDiseaseDB, the details of disease-associated genetic variants and their affected m⁷G sites are provided. Users can further filter the variants for information related to ClinVar or GWAS database. In addition, m7GHub provides four search modes to quickly query the databases (m7GDB and m7GDiseaseDB): by Gene, RsID, Disease, and Chromosome region. The JBrowse Genome Browser is also available for exploring a genomic region of interest. Lastly, m7GHub also provides a detailed help document, and all the materials presented in database and web server can be freely downloaded.

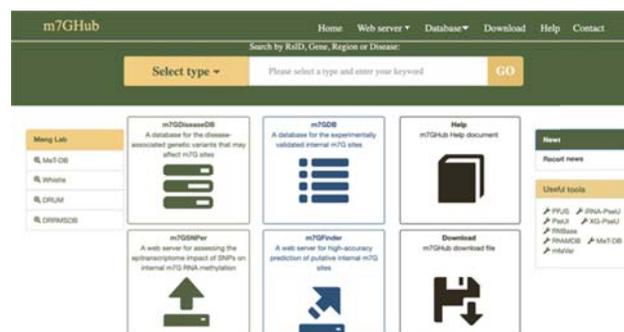

Fig. 3. Homepage of m7GHub. The four main components can be easily accessed from the homepage. m7GHub also provides a search bar for quick query of the database contents by Gene, RsID, Disease, and Chromosome region. The m7GHub website also features with detailed help documents, and all the contents can be freely downloaded.

4 Conclusion

With recent advances in high-throughput sequencing techniques, widespread occurrence of internal mRNA m⁷G modification has been revealed (Chu, et al., 2018; Enroth, et al., 2019; Malbec, et al., 2019; Marchand, et al., 2018; Zhang, et al., 2019). We present here, m7GHub, a comprehensive platform for deciphering the location, regulation and pathogenesis of internal mRNA m⁷G methylation. The platform provided the first collection of 44,058 previously reported internal mRNA m⁷G sites identified under different conditions (m7GDB) by different techniques; a newly developed high-accuracy predictor of internal mRNA m⁷G sites that outperformed existing methods (m7GFinder); the first web server for evaluating the impact of genetic mutations on the m⁷G methylation status (m7GSNPer); and the first database documenting the inferred 1,218 associations between 681 diseases and the m⁷G methylation sites located on 716 genes unveiled via disease-associated genetic mutations (m7GDiseaseDB). We also provided the website with rich functional annotations, user-friendly interfaces and detailed documenta-

tion. In summary, m7GHub (www.xjtlu.edu.cn/biologicalsciences/m7ghub) will serve as a useful resource for studies of the internal mRNA m⁷G modification in human.

Author contributions

K.C. conceived the idea and initialized the project; B.S., K.C. and J.M. designed the research; Z.W. constructed the genomic features considered in site prediction; K.C. processed the raw data and constructed the m⁷G site prediction model; B.S. performed analysis related to site prediction, mutation, annotation and disease association; Y.T. built the website; B.S. drafted the manuscript. All authors read, critically revised and approved the final manuscript.
