10 microstructural evolution, numerical modelling

11

12 **Abstract**

13 Diffusion creep is a fundamental mechanism by which Earth materials deform, but the way

14 microstructure evolves during diffusion creep remains poorly understood, because the

15 mechanism does not leave behind abundant microstructural indicators. Because most rocks are

16 polyphase, this study used numerical simulations to investigate the influence of large second-

17 phase grains on the microstructural evolution of a fine-grained matrix during diffusion creep

18 in both pure and simple shear. The results of the modelling show that large second-phase grains

19 create stress heterogeneities that focus the effects of diffusion creep, which can lead to a

20 profound drop in strength of a material, and dictate where grain boundary sliding surfaces

21 develop within the fine-grained matrix. Rotations of matrix grains are strongly influenced by

22 the rotation direction and velocity of the large grain, especially those that lie adjacent to it. The

23 rotation direction of large grains is not simply either synthetic or antithetic to the shear

24 direction. Instead, rotation directions of large grains can change due to interactions with the

25 matrix. Such interactions could result in simple strain paths producing complex microstructures

26 which could be misinterpreted to record much more complicated strain histories.

27

28 **1 Introduction**

29 The geodynamic behaviour of the Earth is dependent on the physico-chemical properties of the

30 Earth material being deformed, which itself is dependent on that material's metamorphic and

31 deformation history. A rock's microstructure (texture) contains detailed information about the

32 deformation and metamorphic processes that were operative during its history, provided

33 geologists can correctly interpret the microstructural features. One aspect of textural

34 interpretation that remains elusive is exactly how a microstructure evolves during diffusion

35 creep.

36 Diffusion creep is a fundamental process in the Earth's lower mantle (Ammann et al., 2010;

37 Karato and Li, 1992; Karato et al., 1995; Mohiuddin et al., 2020; Ritterbex et al., 2020), upper

38 mantle (Hiraga et al., 2010; Hirth and Kohlstedt, 1995; Karato and Wu, 1993) and crust (Bell

39 and Cuff, 1989; Kilian et al., 2011; Rosenberg and Stünitz, 2003; Rybacki and Dresen, 2000;

40 Rybacki et al., 2006). In the mid-to-upper crust (to a depth of some 20 km), water is abundant.

41 For example, in the fractured upper crust, an interconnected, fluid-filled network of pores

42 characteristically makes up on the order of 1 vol%, and the crust behaves hydrologically like a

43 homogeneous infinite aquifer (Bucher and Stober, 2010). Porosity vanishes below the brittle-

44 viscous transition (~12–15 km depth) but water remains adsorbed to grain boundaries, and

45 occurs in hydrous phases and fluid inclusions (Bucher and Stober, 2010). In the presence of

46 fluid, diffusion-dominated deformation is termed pressure solution or dissolution-precipitation

47 creep (Menegon et al., 2008; Rutter, 1976; Rutter, 1983; Wheeler, 1992; Wintsch and Yi,

48 2002). It is important to recognise that pressure solution occurs by diffusion of material along

49 stressed H_2O-rich grain boundary films, which have different physical properties and chemical

50 behaviour to pockets of fluid that, for example, may collect in pores (Gratier et al., 2013;

51 Wheeler, 1992). Hence, the processes of pressure solution and diffusion creep are equivalent

52 and can be described by exactly the same equations (Elliott, 1973). The presence or absence of

53   a crystallographic preferred orientation (CPO) is commonly used to distinguish deformation

54   by dislocation creep and diffusion creep. During dislocation creep a CPO is developed due to

55   slip on specific crystallographic planes and in specific crystallographic weakening directions

56   (Karato et al., 2008). During diffusion creep, a CPO is traditionally not expected to develop,

57   and any pre-existing CPO is expected to be diminished or destroyed by rotations associated

58   with grain boundary sliding (GBS), which is required for the material to maintain continuity

59   during grain shape change (Elliott, 1973). The dominant deformation mechanism by which

60   different parts of the mantle deform is inferred from an observed presence or absence of seismic

61   anisotropy, where its presence is interpreted to be a product of preferentially aligned crystals,

62   indicating dislocation creep (e.g. Karato et al., 2008; Skemer and Hansen, 2016). Where

63   seismic anisotropy is absent, diffusion creep has been proposed to dominate deformation

64   (Karato and Wu, 1993).

65   Recent advances in our understanding of how diffusion creep operates in rocks have brought

66   some of these ideas into question. A growing list of authors have reported evidence of CPOs

67   developing during diffusion creep under specific conditions (Bons and den Brok, 2000; Díaz

68   Aspiroz et al., 2007; Getsinger and Hirth, 2014; Gómez Barreiro et al., 2007; Imon et al., 2004;

69   Miyazaki et al., 2013; Shelley, 1977; Sundberg and Cooper, 2008). More pertinent to the

70   current study are results that show a CPO can be preserved or modified without being wiped

71   out during diffusion creep. For example, Jiang et al. (2000) showed that an inherited CPO could

72   be preserved to high strain in albite during diffusion creep. Wheeler (2009) used a numerical

73   model to show that seismic anisotropy could be preserved during diffusion creep in a

74   monophase material due to the suppression of grain rotations during deformation. Grain

75   rotations were inhibited by slight elongation of grains, which occurred when diffusion creep

76   rates were fast compared to grain growth rates. Grain elongation occurs during diffusion creep

77   because dissolution at faces experiencing highest normal stress and precipitation at faces

78   experiencing lowest normal stress results in 'flattening' of grains (e.g., Rutter, 1983). Grain

79   growth, or annealing, results in more equiaxed grains, so if this is fast compared to diffusion

80   creep, grain elongation is inhibited (Wheeler, 2009). In contrast to such observations, Elliott

81   (1973) noted that if the strain path during diffusion creep is coaxial and grains do not rotate,

82   then as grains become more elongate, diffusion paths will get longer, and so the process in

83   theory could become self-exhausting. In practice this does not happen, because even on a

84   coaxial strain path, grains continuously rotate with respect to each other because of GBS. Such

85   rotations bring different crystal faces into contact, so newly precipitated parts of grains become

86   subject to dissolution, which tends to keep grains equiaxed. For the most part, coaxial

87   deformation is a rare case, only occurring locally within a body of deforming rock, and bulk

88   coaxial deformation in natural rocks is often partitioned into zones of opposite-sense non-

89   coaxial strain (e.g. Bell et al., 2004). Typical non-coaxial strain paths will tend to keep grains

90   equiaxed. Thus, the link between diffusion creep, grain rotations, and CPO development,

91   preservation and/or annihilation remains ambiguous.

92   Nearly all rocks are polyphase, and a number of previous numerical models have explored the

93   interaction between different phases during deformation (e.g. Carreras et al., 2013; Dabrowski

94   et al., 2012; Jessell et al., 2009 and references therein; Johnson, 2008). The rotation behaviour

95   of large rigid grains embedded in a lower viscosity fine-grained matrix during deformation has

96   been of particular interest because large grain rotations can record regional-scale strain

97   histories (e.g. Holcombe and Little, 2001; Passchier and Trouw, 2005, and references therein).

98   Microstructures such as spiral garnets have commonly been interpreted to record substantial

99   rotation of porphyroclasts (Rosenfeld, 1970), although debate remains as to whether such

100   patterns truly record rotation of large grains relative to geographic coordinates (e.g., Aerden

101   and Ruiz-Fuentes, 2020; Bell and Johnson, 1989; Johnson, 1993; Williams and Jiang, 1999).

102   However, previous studies of inclusion trails have also shown that rotation of large grains can

103   be supressed in deformed metamorphic rocks. For example, Steinhardt (1989) showed that

104   porphyroclasts in non-coaxially deformed schists had undergone very little or no rotation

105   during deformation relative to one another on the scale of an entire outcrop (tens of metres).

106   Studies on the regional scale have also shown a lack of porphyroblast rotation in the Otago

107   schists (Johnson, 1990; inclusion trails consistently oriented over 3000 km^2), the Lys-

108   Caillaouas Massif in the Variscan Pyrenees (Aerden, 1995; inclusion trails consistently

109   oriented over tens of km^2), the Variscan Iberian Massif (Aerden et al., 2020), and many other

110   places (see references in Fay et al., 2008 for other examples).

111   As a result of the controversy surrounding whether rigid objects rotate or not during non-

112   coaxial deformation, a large number of modelling studies have focused on the issue. A

113   summary of the previous literature can be found in Table 1 of Griera et al. (2013). For example,

114   Fay et al. (2008) used finite element modelling of material with Mohr-Coulomb plasticity to

115   show that anastomosing shear zones can develop around large strong rigid objects in a

116   relatively fine-grained and weak matrix, because of stress concentrations generated around the

117   large grains during initial shortening. When shear zones develop, no large grain rotation

118   occurred, and if such shear zones were absent, large grains did rotate. Griera et al. (2011) note

119   that experiments and numerical simulations that use viscous matrix rheologies result in the

120   rotation of porphyroclasts, whereas those using Mohr-Coulomb rheologies generally result in

121   non-rotation. Using a full-field crystal plasticity method in the *Elle* microstructural modelling

122   suite (Bons et al., 2008), Griera et al. (2011) explored the effects of an anisotropic

123   polycrystalline matrix deforming by dislocation creep on large grain rotation. Their results

124   suggested that the rotation of large grains is strongly dependent on the degree of anisotropy in

125   the matrix grains, with more anisotropic matrix grains leading to the development of shear

126   bands that inhibit the rotation of large grains.

127   Numerical models of large grain rotations in a matrix deforming by diffusive mass transfer are

128   so far lacking. In diffusion creep, Wheeler (2009) showed that grain elongations do not have

129   to be very large before they significantly impact grain rotations in monophase aggregates, but

130   microstructural evolution within a polyphase sample depends strongly on how the different

131   phases interact mechanically (e.g. Jessell et al., 2009). The viscosity of a polymineralic rock

132   undergoing pressure solution can be much lower than its monomineralic counterparts, as

133   predicted theoretically (Wheeler, 1992) and observed in experiments (Sundberg and Cooper,

134   2008; Zhao et al., 2019). Grain boundary diffusion creep is also more efficient in fine-grained

135   rocks as the length of diffusion pathways (i.e. grain boundary segments) are small, so the

136   inhibition of grain growth by boundary pinning affects creep rates in multiphase materials.

137   Variation in grain size within a sample may have a local effect on distribution of stress, and

138   therefore how a given microstructure responds to an imposed far-field stress. Many of the

139   factors that control how the microstructure of a polyphase rock may evolve during diffusion

140   creep remain to be tested.

141   Previous attempts at modelling the influence of a large second-phase grain on the evolution of

142   a polycrystalline material deforming by diffusion creep have been made using the same

143   modelling software employed in this study (described fully in section 3). Berton et al. (2006)

144   investigated the development of fibrous pressure shadows at the interface between a rigid

145   object and a fine-grained matrix of different compositions in a two-phase composite deforming

146   by pure shear. Those authors showed that the ratio of $CaCO_3$ diffusion rate along calcite-pyrite

147   versus calcite-calcite boundaries strongly influenced pressure shadow growth, sliding and

148   rotation of matrix grains, and the orientation of strain axes around the rigid object, which

149   suggests that purely physical models of ductile flow around rigid clasts in rocks do not capture

150   the complexity of microstructural evolution during diffusive mass transfer-driven deformation.

151 Berton et al. (2011) advanced these conclusions by exploring the effects of inclusion size and

152 boundary smoothness on pressure shadow growth, again during pure shear.

153 Here we present the first models for the effects of a large grain sitting in a fine-grained matrix

154 of different mineralogy, during deformation by diffusive mass transfer in both pure and simple

155 shear. We show how rotations and angular velocities of both the matrix grains and the large

156 grain evolve with increasing strain, and discuss how such changes affect CPO modification

157 and stress evolution in the model.

158 **2 Fundamental aspects of pressure solution and grain boundary diffusion (Coble) creep**

159 Elliott (1973) showed that the processes of pressure solution and grain boundary diffusion

160 creep are equivalent, and flow laws have the same mathematical form, except that pressure

161 solution may be faster due to fast diffusion along aqueous grain boundary films rather than

162 along essentially dry grain boundaries. The most fundamental link between stress (a physical

163 property) and diffusion (a chemical process) comes from the driving force for diffusion, which

164 is the gradient in chemical potential, μ, defined as:

165 $$\mu = F + \sigma_n V \qquad\qquad (1)$$

166 where σ_n is compressive normal stress across the interface, F is the molar Helmholtz free energy

167 of the solid, V is the molar volume of the solid. Strictly, μ is the chemical potential of the solid

168 in an adjacent 'phase' in which it can dissolve, and the 'phase' in this case is actually the grain

169 boundary region. Eq. (1) shows that as normal stress increases on an interface, the chemical

170 potential of the material next to that interface will also increase, that is it will dissolve more

171 readily. Grain boundaries under higher normal stress will therefore have a higher chemical

172 potential than grain boundaries under lower normal stress, which in turn results in a gradient

173 in chemical potential along grain boundaries, and between different boundaries of the same

174 grain (Fig. 1a). These gradients drive diffusion of material resulting in shape change. Variations

175   in normal stress can then give rise to gradients along interfaces (enabling Coble creep) and

176   within grains (enabling Nabarro-Herring creep).

177   Building on this fundamental relationship between stress and diffusion, Coble (1963) analysed

178   diffusion creep of spherical grains of diameter a to find a linear relationship between stress and

179   strain rate for pure shear. This relationship was revised by Raj and Ashby (1971) and Poirier

180   (1985), and can be rewritten in terms of the shear stress to obtain the equivalent Newtonian

181   viscosity η (following Eq. (7.14) of Poirier, 1985):

182    $$\eta = \frac{1}{141}\frac{kTa^3}{Dw\Omega} = \frac{1}{141}\frac{RTa^3}{DwV} \qquad\qquad (2)$$

183   where k is Boltzmann's constant, R is the gas constant, T is temperature, w is grain boundary

184   width, D is the diffusion coefficient, Ω is atomic volume, V is molar volume and a is grain size

185   (diameter). This derivation assumed a spherical grain embedded in a medium with a simple

186   stress system, so does not encompass the actual geometries of interlocking grains. To address

187   this, Raj and Ashby (1971) modelled arrays of regular hexagons, but in such models each grain

188   is identical and behaves the same way, so processes such as the reduction of CPO strength by

189   grain rotation cannot be modelled. In such models, either the grains do not rotate and instead

190   become elongate if grain boundary sliding is allowed to occur by two orthogonal 'modes' of

191   sliding, or all the grains rotate the same amount and need not show any shape change, if sliding

192   occurs by one dominant mode (Raj and Ashby, (1971). Ford et al. (2002) and Ford et al. (2004)

193   thus went further, to model an arbitrarily complex space-filling array of grains. The model was

194   extended to include an insoluble second phase (Berton et al., 2006; Berton et al., 2011), and to

195   encompass spatially periodic microstructures (Wheeler 2009).

196   Grain boundary sliding is intrinsic to diffusion creep (Raj and Ashby, 1971). This leads to

197   collisions between triple junctions followed by neighbour switching, as first modelled by

198   Ashby and Verrall (1973). Spingarn and Nix (1978) pointed out the grain shape change during

199   neighbour switching predicted in Fig. 4 of Ashby and Verrall (1973; redrawn in Fig. 1b) was

200   incorrect, and presented a correct model, as shown and described in Figure 1c. Our modelling

201   reproduces that behaviour when starting with a microstructure of regular hexagons. Some

202   previous modelling of diffusion creep has encompassed finite grain boundary sliding viscosity

203   (Wheeler 2010). This leads to a modified grain size dependence in the flow law, for which

204   there is no clear support from experiments, and in the current model we set the grain boundary

205   shear stress to zero.

206

207

208

209
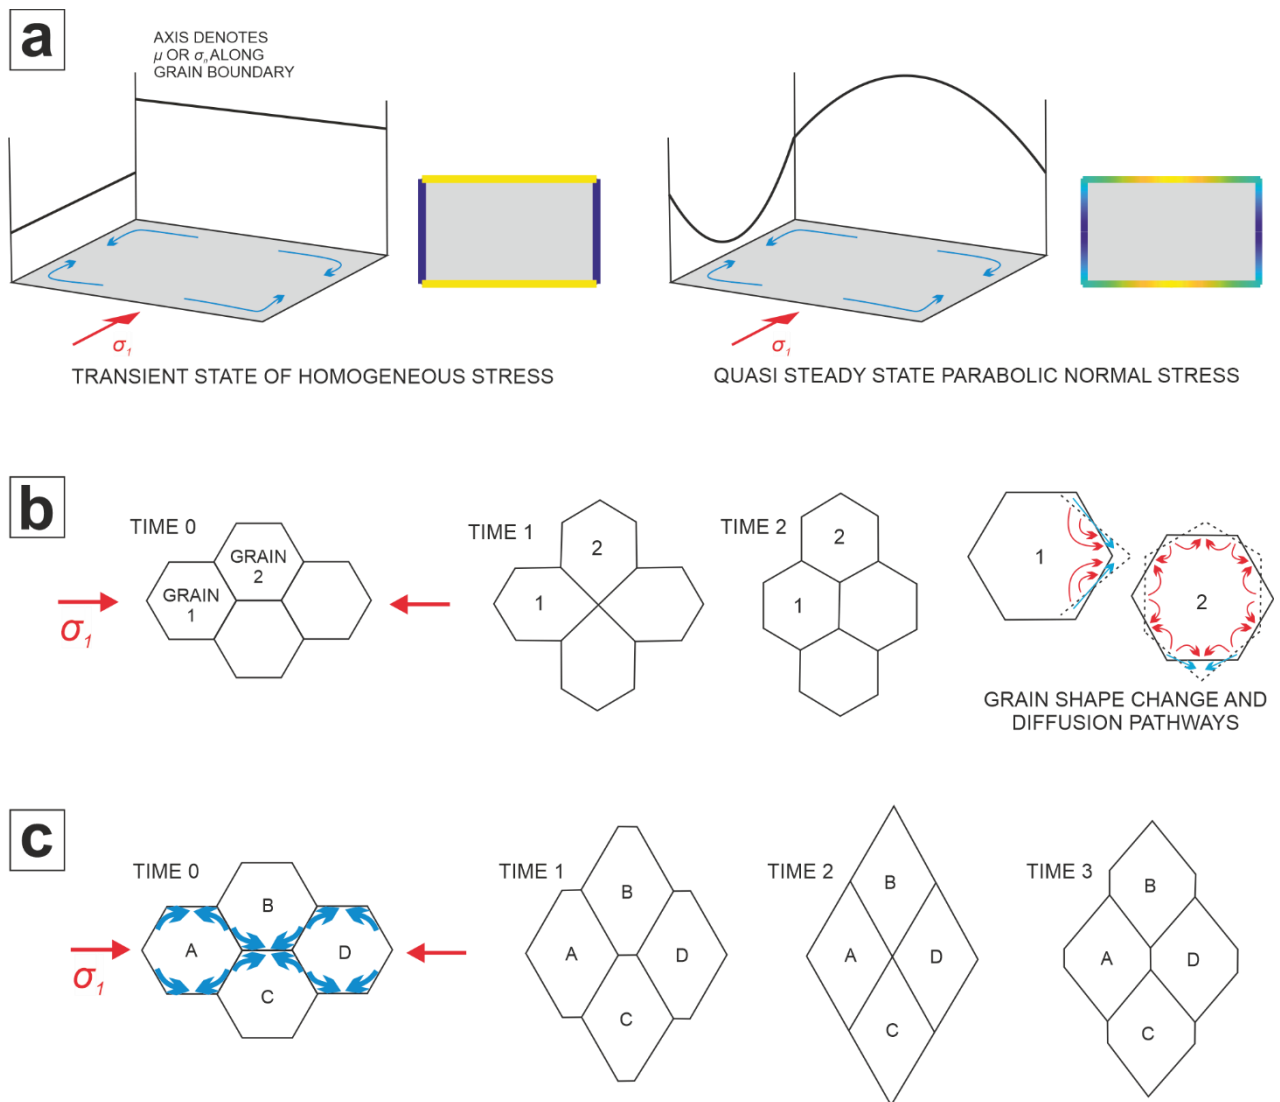

Figure 1 *Stresses and neighbour switching during diffusion creep. a) Initial and steady state*

stresses during diffusion creep of a rectangular grain microstructure. Normal stress evolves

to a parabolic distribution during diffusion creep or pressure solution, and is visualised

either by plotting it in the third dimension (redrawn from Fig. 1 of Wheeler, 1992, and see

"Stresses" movies in the supplementary information), or colour coding it along boundaries

in 2D (as used in Figs. 5 and 9). b) Shape change at three consecutive stages during diffusion

creep, as represented incorrectly in the Ashby-Verrall neighbour switching model (redrawn

from Figs. 4 and 7 of Ashby and Verrall, 1973). Dashed boundaries show final grain shape,

red curved arrows show bulk diffusive flux, blue straight arrows show boundary diffusive

flux. The model cannot be right because grains begin with identical shapes and are subject to

220   *identical imposed stress, yet grain shapes are then illustrated as evolving differently (for*

221   *details see Spingarn and Nix (1978)). c) Progressive shape change during neighbour*

222   *switching in diffusion creep is correctly depicted in Fig. 7 of Spingarn and Nix (1978);*

223   *slightly modified here to highlight boundary diffusive flux pathways (blue arrows). All fluxes*

224   *are symmetric and grains evolve in identical ways in accord with their identical initial*

225   *shapes. For initial regular hexagons the DiffForm modelling software reproduces the*

226   *evolution shown. Spingarn and Nix add a final stage in which interface energy plays a role,*

227   *but this is not included in our current model.*

228

229   Wheeler (1992) found it useful to use Onsager diffusion coefficients L $(= Dc/RT)$, where D is

230   the conventional diffusion coefficient, c is concentration, R is the gas constant, and T is absolute

231   temperature, to describe diffusion of each chemical component during creep in multiphase

232   systems. D as used in Fick's law is insufficient to model diffusion creep as it represents

233   diffusion proportional to a gradient in concentration, whereas diffusion in solid-state systems

234   is more accurately described by assessing gradients in chemical potential, μ. μ is incorporated

235   into the Onsager diffusion coefficient so its use is more appropriate than D in models of solid-

236   state diffusion. When multiplied by grain boundary width w, $A = wL$ describes the overall ease

237   of diffusion along a boundary (Eq. (4) in Wheeler, 1992). The net chemical current along a

238   grain boundary is a function of the 'conductances', A, of all components that comprise the

239   system. With several chemical components, A is a matrix and it proves useful to define its

240   matrix inverse, K (Eq. (5) in Wheeler, 1992). K values relate to the 'resistances' (or the inverse

241   of the 'conductances') of each component to dissolution or growth by diffusion along the grain

242   boundary (Wheeler, 1992). In the model we discuss here, the second phase is insoluble and the

243   mathematics is simplified. With one soluble phase we define one chemical component with a

244 formula identical to that phase, and $K = 1/A$ (Eq. (6) of Wheeler, 1992). This means that for

245 spherical grains, from Eq. 2:

246 $$\eta = \frac{1}{141}\frac{RTa^3}{Dw\mathrm{V}} = \frac{1}{141}\frac{a^3}{wL\mathrm{V}^2} = \frac{1}{141}\frac{Ka^3}{\mathrm{V}^2}$$ (3)

247 The model we present is grain scale and so provides precise details of grain rotations and

248 viscosity evolution. The viscosity still scales with grain size etc. in accord with Eq. 3 but the

249 key enhancement is that the single dimensionless number here (1/141) is replaced by an

250 evolving and anisotropic function of microstructure. Elliott (1973) recognised that evolving

251 grain shape changes viscosity; our model captures the more general dependence on

252 microstructure. In addition, Wheeler (2010) showed that mechanical anisotropy develops

253 during diffusional creep that includes a component of boundary sliding, which it always does

254 (Raj and Ashby, 1971). The consequence of this is that as grain rotations occur, grains can

255 become aligned in 'weak' or 'strong' directions with respect to the direction of maximum

256 shortening. Consequently, the viscosity at each time depends on the microstructure and the

257 orientation of strain rate axes relative to that microstructure. Eq. 3 provides a "benchmark"

258 value for comparison between idealised spherical grains and more complex microstructures

259 with the same average grain size.

260 **3 Methods**

261 Diffusion creep modelling was performed using the C++-based modelling suite DiffForm, and

262 the results were visualised in MATLAB® using the DiffView software (Berton et al., 2006;

263 Berton et al., 2011; Ford et al., 2002; Ford et al., 2004; Wheeler, 2009; Wheeler and Ford,

264 2008). A rigorous treatment of the fundamental mathematics used by DiffForm can be found

265 in Wheeler and Ford (2008) and Wheeler (2009)**.** The intention here is to attempt to describe

266 how DiffForm works in a way accessible to non-mathematicians, to emphasise the physical

267 processes that are being modelled.

268   Wheeler (1987) showed that the ideal distribution of stress (i.e. the chemical potential) along a

269   boundary has a parabolic shape (Fig. 1a; distribution is cubic if there are relative grain

270   rotations), toward which all other stress distributions evolve, with the consequence that

271   material can be dissolved or precipitated at all points along the boundary. The flux, and

272   therefore the current (i.e. the flux $\times$ the boundary width; Wheeler and Ford, 2008), can be

273   determined at any point along the boundary, so dissolution and precipitation rates can be

274   calculated for a given imposed normal stress. The divergence speed of any two adjacent grains

275   can be calculated from the dissolution and precipitation rates at grain boundaries. Because

276   grains are rigid and do not experience internal deformation, the relative motions of grains must

277   be equivalent to their relative velocity plus a rotation around a reference point. As no internal

278   deformation is assumed by the model, overgrowths must be either of constant width or wedge-

279   shaped.

280   A set of simultaneous equations are solved to determine instantaneous velocities and angular

281   velocities of grains, and stresses along each boundary. After each strain increment is applied,

282   the microstructure is modified by repositioning grain boundaries in the middle of overgrowths

283   and regions of dissolution. Triple junctions that overlap at any stage, representing the neighbour

284   switching events common to GBS (Spingarn and Nix, 1978) are redrawn. The resultant

285   microstructure is then used to solve for new velocities and streshses. Note that stress is not

286   actually imposed on the model microstructure; instead an average strain rate tensor is imposed,

287   for which the simultaneous equations are then solved to predict the average stress and the local

288   stresses on grain boundaries, which in turn drive shape change.

289   There are three inputs to the program.

290   **Input 1. The initial grain geometry ("net")** shown in Figure 2 was used to test how the

291   presence of a large second phase grain might impact the microstructural evolution of a fine-

292 grained monophase matrix deforming by diffusion creep. This starting "net" was translated into

293 the input format used for DiffForm from the input format used for Elle (Piazolo et al., 2010).

294 This topology is roughly analogous to the porphyroclasts/blasts often found in metamorphic

295 rocks, or the phenocrysts commonly observed in igneous lithologies. The matrix grains are

296 designed to exhibit a shape preferred orientation, or shape fabric, which is again commonly

297 observed in both metamorphic and igneous rocks. The shape fabric of the matrix is simplified

298 to allow clear identification of any effects the large grain may have on matrix-grain evolution.

299 The possible effects of the matrix grains all having exactly the same shape, size and shape

300 orientation, compared to the heterogeneity of grain shape and size found in natural samples, is

301 discussed in section 5.4.

302
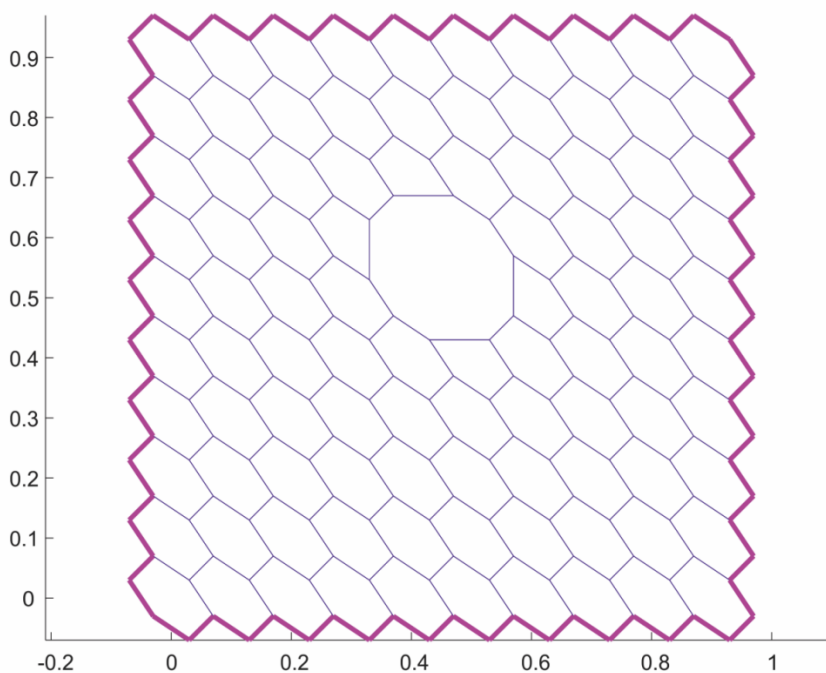

303

304 ***Figure 2*** *Starting geometry of model runs. Blue lines represent grain boundaries. The large*

305 *central grain is defined to be of a different composition to the matrix grains. Scale is arbitrary*

306 *in the model.*

307 **Input 2. 'K values' (resistances) for each component and molar volumes for each phase.**

308 Here the second phase is required to be insoluble, but this would imply an infinite *K* so instead

309 the *K* value is set to a large but finite value. A key point is that model outputs scale in a simple

310 way with regard to parameters. The stress scales in accordance with Eq. 3. Grain angular

311 velocities scale in accordance with strain rates, for each particular imposed strain geometry.

312 This means that the choices for *K*, *V* and the grain size in the starting net will not affect the

313 model outputs, except for the stress levels, for which scaling is simple.

314 With this in mind 'legacy' values of various coefficients are used in the program. In the model

315 runs presented here, the matrix grains were defined to have the composition of calcite, $CaCO_3$,

316 and the large grain was defined as pyrite, FeS_2. These were used in Berton et al. (2006) and

317 have not been changed subsequently, but we emphasise that our models make predictions about

318 any insoluble mineral embedded in any mineral that is undergoing pressure solution or

319 diffusion creep. The parameters used in the DiffForm input file for our experiments are:

320 Average grain area for soluble phase $G = 0.01$ m^2

321 Diameter of equivalent circle $a = ((4/\pi)G)^{1/2} = 0.112$ m

322 $V = 3.693 \times 10^{10}$ m^3/mol

323 K[$CaCO_3$, $CaCO_3$]$= 2 \times 10^{18}$ Pa.s m^3 mol^{-2}

324 From which we find, from Eq. 3, a viscosity for equivalent spherical grains of 1.461×10^{-8} Pas

325 – unrealistically small but needed only as a benchmark with which to compare model outputs.

326 **Input 3. Strain geometry, rate and timestep.** In all experimental runs presented here, the

327 starting net was set up to undergo at least 200 increments of either pure or simple shear at a

328 strain of 0.5 per time step, with a time step length of 0.01 s. Multiplying strain by time step

329 length results in a strain of 0.5% being imposed on the model per time step, so that 100% strain

330   would be achieved after 200 time steps). Time step length, and therefore strain rate, are

331   arbitrary as there is a linear relationship between angular velocity and overall strain rate in the

332   model (note this is on the scale of the whole model, as opposed to the angular velocities of

333   individual boundaries. In our model, boundaries cannot be used as passive markers as grains

334   undergo dynamic shape change), so faster strain rates simply mean the microstructural

335   evolution occurs more quickly, but the final microstructure produced is identical (see Wheeler,

336   2009, for more details).

337   One consequence of the legacy coefficients is that values for stress in the model are small. The

338   stress evolution of the model runs presented here are discussed fully in section 5.3. The small

339   values for stress do not affect the predictions of how the microstructure evolves, since these

340   depend on finite strain and are independent of strain rate; nor do they affect the predicted

341   angular velocities, since these scale with strain rate.

342   DiffForm models are spatially periodic (in essence, infinite) thus avoiding the undue influence

343   of model boundaries in small finite models. The model tracks changes in the starting

344   microstructure as it evolves along either coaxial (pure shear), non-coaxial (simple shear), or

345   mixed strain pathways. DiffForm has been continually developed over the last two decades

346   (Berton et al., 2006; Berton et al., 2011; Ford et al., 2002; Ford et al., 2004; Wheeler, 2009;

347   Wheeler and Ford, 2008), with the most recent advancements allowing the modelling of two-

348   phase materials. Due to computational limitations, some starting geometries terminate after

349   accumulating only very small strains. Once a starting geometry that can accumulate high strains

350   has been defined, the time required for each model run is on the order of a few days.

351   In the model runs presented here, the matrix grains have a shape-preferred orientation. This

352   helps to give each grain an anisotropic rheology, which is common in natural crystals, and a

353   key component of accurately modelling the deformation of polycrystals (e.g. Griera et al.,

354 2013). Although the strong SPO is a simplification of the greater shape heterogeneity observed

355 in natural microstructures, the effects of which are discussed in section 5.4.1, to our knowledge

356 this is the first study that presents results of the effects of a matrix with anisotropic rheology

357 deforming by diffusion creep on the rotation behaviour of a large rigid object.

358 **4 Results**

359 *4.1 Pure shear*

360 The starting net shown in Figure 2 was deformed in both pure and simple shear. The model

361 output files presented in the figures, together with software ("DiffView") allowing

362 visualisation of grain movements, stresses, and so on are available from the authors on demand.

363 Numerical experiments performed using DiffForm eventually terminate because of problems

364 with the evolving topology of the net (neighbour switching in particular; see section 5.4). If

365 these occur at the edge of the net as represented in the model, there are a number of scenarios

366 and some are difficult to deal with, hence the program terminates. The pure shear experiment

367 terminated at 130 time steps, i.e. achieved a strain of 65%. Four strain increments of the

368 microstructural evolution are presented in Figure 3a–d. Grains in Figure 3 are coloured by the

369 finite rotation they have undergone from their original orientation, in degrees (readers are

370 referred to the Pure_fin_theta simulation in the supplementary materials for an animation of

371 evolution of finite rotations throughout the entire experiment). Note that the colour scale

372 changes for each strain increment presented in Figure 3, to allow visualisation of larger finite

373 rotations as deformation proceeds. The colour scale limits are set to the maximum rotation in

374 each frame, and are changed in each plot so that the contrast between the largest and smallest

375 rotations at each time increment can easily be seen. In contrast, the animations in the

376 supplementary materials are set up so that the colour scale limits are the same for all frames.

377 This leads to differences in rotations in the earliest stages of the model run being somewhat

378 obscured by the colour scheme, because the rotations are small relative to the colour scale

379   limits. Figure 3a shows that, by a strain of about 0.16, most matrix grains have rotated about

380   the same amount as the large grain (~15°), with the exception of a row of grains whose rotations

381   appear to be subdued by their alignment with the long axis of the large grain (at an angle of

382   approximately 55° to the direction of maximum shortening) and so have only rotated some 10°.

383   Figure 3b shows a similar trend, with distinct regions of the matrix undergoing different finite

384   rotations depending on their geometric relation to the large grain. The band of lowest rotations

385   sits at 60° to the maximum shortening direction. By a strain of about 0.49 (Fig. 3c), the band

386   has flattened to around 70° with respect to the maximum shortening direction, but the influence

387   of the large grain is no longer apparent along the entire band. Instead, most matrix grains that

388   do not neighbour the large grain have rotated more (some 45°) than the large grain itself (closer

389   to 35°), and matrix grains that neighbour the large grain either have lower or higher finite

390   rotations than the bulk matrix. By the last stage, a 'sliding surface' (perhaps a shear band) that

391   links up across multiple grains has formed (this is best seen in the animation in the online

392   supplementary information), at an angle of 75° to the maximum shortening direction (Fig. 3d).

393   The sliding surface is composed of aligned boundaries of grains that undergo the smallest

394   rotations in the early stages of deformation, so its development is fundamentally related to the

395   presence of the large grain. By the time the model terminates, it has undergone a longitudinal

396   strain of roughly 0.65. The model retains a constant area, a useful check that the mass

397   conservation equations built into the code are satisfied. We note that under certain conditions

398   (e.g. cleavage development as described in Bell and Cuff, 1989), pressure solution can result

399   in substantial volume loss; here we are considering the simplest case.
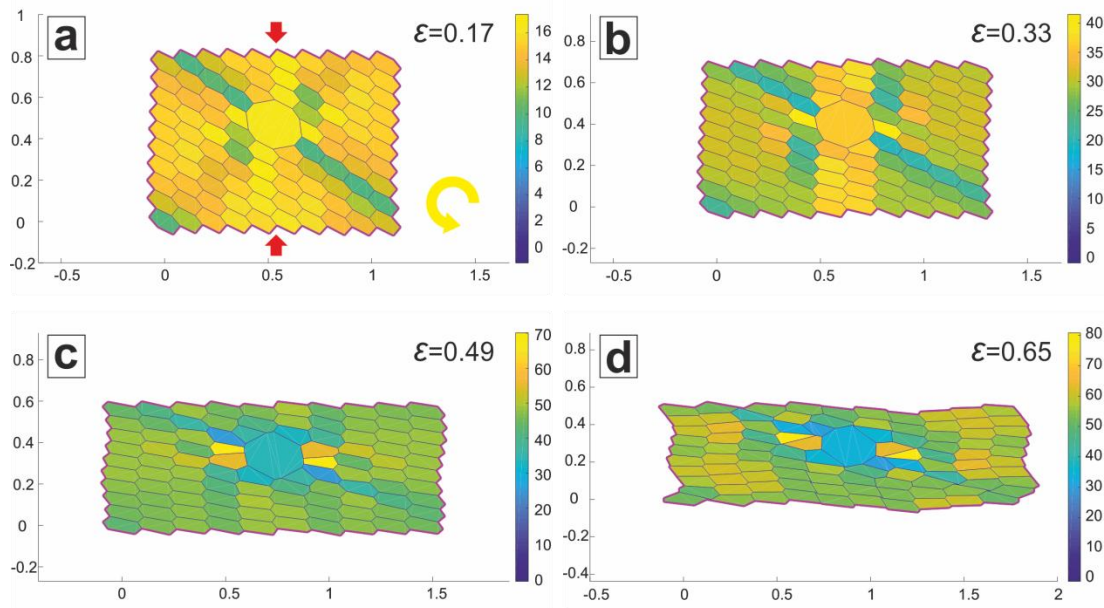

Figure 3 *Results of the pure shear experiment at four strain increments. The model terminated at a strain of 0.65. Grains are coloured by finite rotation with respect to starting orientation in degrees (anticlockwise positive; yellow arrow in (a)). Red arrows in (a) show direction of shortening. Note change in scale for each strain increment; colour scale was altered so unique features can be seen at each stage. For an animation of finite rotations throughout the entire evolution of the model, see the Pure_fin_theta simulation in the supplementary materials.*

Figure 4a shows a plot of the finite rotations of each grain with respect to their initial orientation, with the rotation behaviour of the large grain highlighted as a thick red line. A thick blue line shows the mean rotation behaviour of all matrix grains. Notably, most matrix grain rotations tend to steadily increase in an anticlockwise direction with increasing strain (anticlockwise rotation is defined as positive). This is interpreted to be an effect of the orientation of the strong shape fabric in the matrix with respect to the direction of maximum shortening, and more variation in rotations might be expected in model nets with more heterogeneous grain shapes. The large grain begins rotating in the same, anticlockwise, direction as the matrix grains, but at a strain of about 37% its direction of rotation reverses.

417   This is reflected in a plot of the angular velocities of all grains (Fig. 4c), where the rotation

418   velocity of the large grain initially accelerates, before stabilising at around 60° per arbitrary

419   time unit at a strain of approximately 0.1. The grain then slows and eventually reverses its

420   rotation direction at a strain of 0.37. At this point the red line in Figure 4c crosses the dashed

421   line representing zero angular velocity, as the grain switches from positive to negative rotation.

422   The large grain then begins to accelerate in the new rotation direction until it reaches about 25°

423   per time unit (Fig. 4c), before slowing to around 30° per time unit at a strain of around 0.4.

424   Between 0.4 and 0.6 strain, the large grain's angular velocity is somewhat erratic, first slowing

425   by about half and then accelerating sharply at around 0.56 strain. The large grain rapidly

426   reverses rotation direction again just before failure after achieving a strain of 0.6. Overall, the

427   matrix grains experience a less variable rotation history, with the majority of grains rotating at

428   a fairly constant angular velocity of around 50° per time unit (blue line in Fig. 4c), until a strain

429   of around 0.45. After a strain of 0.45 is reached, this steady-state behaviour in the angular

430   velocities of the matrix grains comes to an end and nearly all grain rotations slow down (mean

431   angular velocity drops to around 20° per time unit; blue line in Fig. 4c), before the matrix grain

432   population undergoes a wide spread in accelerations/decelerations at a strain of about 0.6, just

433   before the model terminates. The spread in angular velocities of the matrix grains appears to

434   be caused by the acceleration in angular velocity of the large grain, which begins just before

435   0.6 strain, and influences matrix grains directly adjacent to it, which then undergo relatively

436   turbulent behaviour compared to grains in the bulk matrix. The large spread in angular

437   velocities of the matrix grains at the end (after 0.6 strain) of the pure shear experiment is

438   qualitatively similar to a large spread in angular velocities of matrix grains at the beginning

439   (~0.1 strain) of the simple shear experiment (see section 4.2). In simple shear, the spread in

440   angular velocities of matrix grains is observed to be associated with a change in angular

441   velocity of the large grain, and a drop in overall strength of the model net. However, because

442 the model terminates directly after this spread occurs in the pure shear model, it is not possible

443 to observe or predict whether angular velocities of grains would return to steady-state

444 behaviour in pure shear. Likewise, mean matrix grain rotations suggest that the microstructure

445 may be asymptotically approaching a rotational steady-state as per Wheeler (2009), but

446 termination of the model makes this difficult to be sure of. Readers are referred to the

447 Pure_fin_theta simulation in the supplementary materials for an animation of angular velocity

448 evolution throughout the entire experiment.

449 The development of the sliding surface by grain boundary alignment has a profound effect on

450 the strength of the model. Differential stress steadily increases with increasing deformation

451 until a critical point, just after a strain of 0.5, is reached (Fig. 4d), i.e. just after the steady-state

452 behaviour of the matrix grains observed in the angular velocity plot ends. As the model

453 terminates, the differential stress evolves along a stress-strain path reminiscent of typical rock

454 deformation laboratory experiments stressed to brittle failure (e.g. the room temperature

455 experiments performed by Tullis and Yund, 1992; see their Fig. 3). The stress-strain curve

456 shows the strength of the material, which initially increases, before dropping substantially just

457 after a strain of 0.5, just before the model run terminates.

467 *stress (i.e. strength evolution of the deforming microstructure) during the model run.*

468

469 DiffForm also models stress evolution on individual grain boundaries. Figure 5 shows grain

470 boundary stresses at four time increments throughout the experiment (readers are referred to

471   the Pure_stresses simulation in the supplementary materials for a 3D animation of grain

472   boundary stress evolution during the experiment). Figure 5a shows that stresses are close to

473   zero on most boundaries at the start of the experiment. Some higher compressional (positive)

474   and extensional (negative) stresses are observed on boundaries with or adjacent to the large

475   grain. In the first quarter of the experiment, stresses increase fairly homogeneously on all

476   boundaries. When a strain of approximately 0.2 is reached, boundary stresses on a column of

477   matrix grains above and below the large grain, in a direction parallel to the axis of maximum

478   shortening in the model, and phase boundaries in the same column, become substantially larger

479   than on other boundaries. The growth of these boundary stresses is most easily visualised in

480   the Pure_stresses simulation in the supplementary materials. As strain proceeds, stress is

481   transmitted to matrix grain boundaries in the same row of grains further from the large grain

482   until a strain of around 0.35, when the maximum stress differences between those grain

483   boundaries and surrounding matrix grain boundaries are reached (Fig. 5b). This coincides with

484   the change in rotation direction of the large grain. After 0.35 strain, stresses are rapidly

485   redistributed onto all matrix grain boundaries, and by a strain of around 0.5, stress magnitudes

486   are roughly equal on all boundaries (Fig. 5c). Subsequently, at the same time as a large spread

487   in angular velocities is observed to occur at a strain of around 0.6, stresses on boundaries in the

488   initial row of grains parallel to the direction of maximum shortening drop rapidly (Fig. 5d), and

489   this behaviour spreads throughout the matrix just before the model terminates (Fig. 5d).
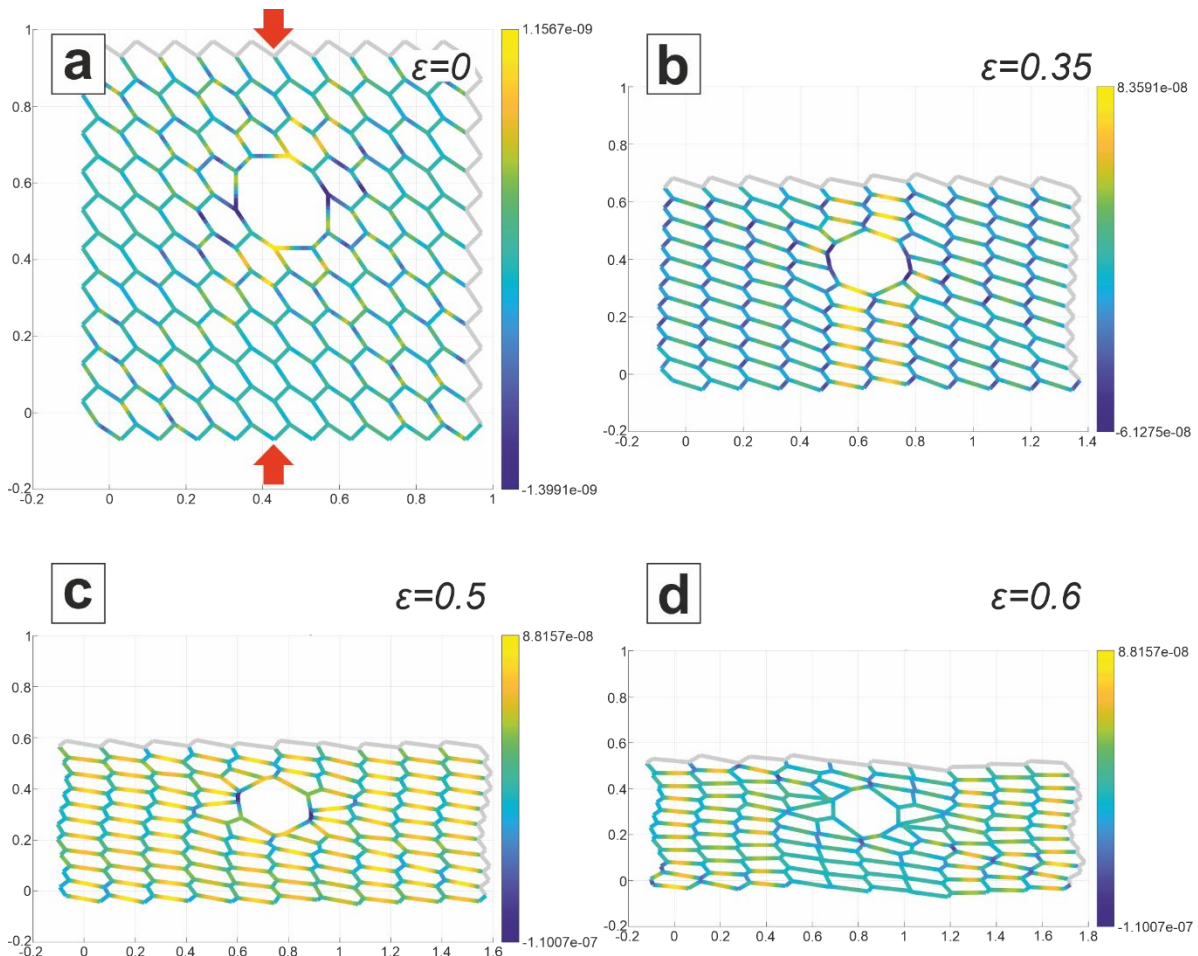

Figure 5 *Grain boundary stresses at four time increments in the pure shear model run. a) At the start of the experiment, stresses on most matrix boundaries are close to zero. Boundaries associated with the large grain show the highest positive (compressive) and negative (tensional) stresses. Red arrows show direction of shortening. b) High compressive stresses first develop on matrix grain boundaries in a column parallel to the axis of maximum shortening above and below the large grain, and on the phase boundaries between the large grain and small grains. c) As strain proceeds, compressive stress develops on other matrix boundaries. d) As the rotation direction of the large grain changes, stress on small grain-large grain phase boundaries, and matrix grain boundaries in a column parallel to the axis of maximum shortening above and below the large grain, drops substantially. With further strain, stress magnitudes on the other matrix grains also drop (see the Pure_stresses simulation in the supplementary material for a 3D animation of the full model run).*

503   *4.2 Simple shear*

504   Dextral simple shear was applied to the same starting geometry as the pure shear experiment

505   (Figure 2). The dextral simple shear experiment reached a strain of 108% (215 timesteps)

506   before terminating. Figure 6 shows four strain increments of the microstructural evolution of

507   the model during simple shear. The Simple_fin_theta and Simple_ang_vel simulations in the

508   supplementary materials show animations of the entire model run. The colour scheme in Figure

509   6 shows finite rotation of grains, in degrees. Note that the colour scale changes between plots

510   to accommodate higher-angle finite rotations at increased strains. The simulations in the

511   supplementary information are set up so that the colour scale limits are the same for all frames.

512   The influence of the large grain on matrix grain rotations is quite different to that observed in

513   pure shear, but equally noteworthy.
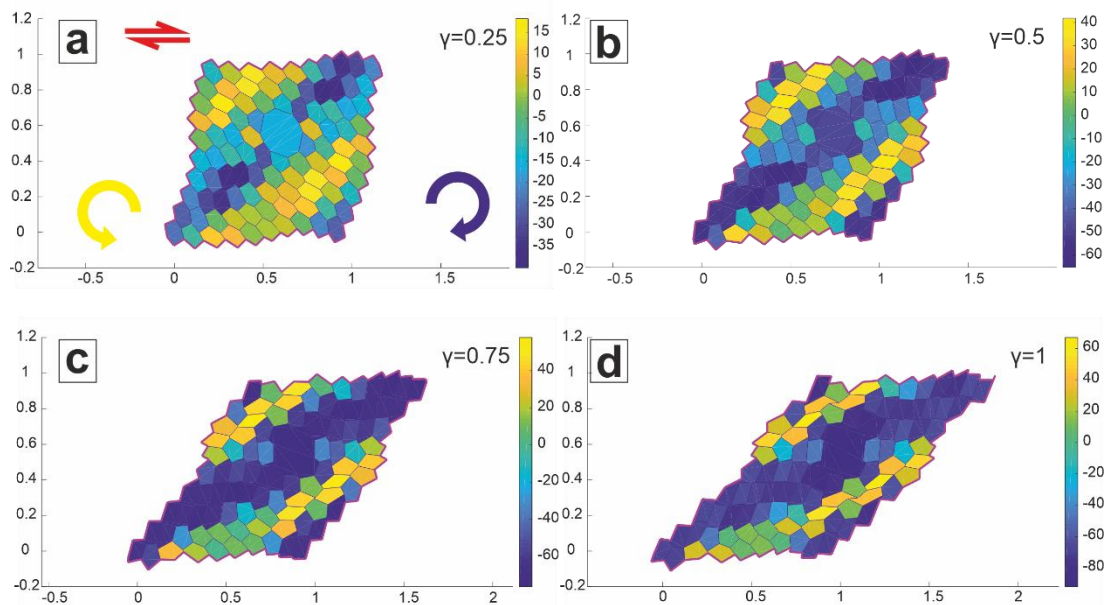

514

515   ***Figure 6*** *Results of the simple shear experiment at four strain increments. The model*

516   *terminated at a strain of 1.08. Grains are coloured by finite rotation with respect to starting*

517   *orientation, in degrees (anticlockwise positive, yellow arrow in (a); clockwise negative, blue*

518   *arrow in (a)). Red arrows in (a) show direction of shear. Note change in scale for each strain*

519   *increment; colour scale was altered so unique features can be seen at each stage. For an*

520   *animation of finite rotations throughout the entire evolution of the model, see the*

521   *Simple_fin_theta simulation in the supplementary materials.*

522

523   Initially, the large grain begins to rotate in a clockwise direction, i.e. synthetically to the

524   imposed shear strain direction. The rotation of the large grain influences a row of grains

525   perpendicular to the shape fabric to rotate in the same direction as itself (seen as a blue band in

526   Fig. 6a–d). Rotation of these grains results in neighbouring grains forming two rows of grains

527   either side of the first (i.e. perpendicular to original shape fabric) that rotate in the opposite

528   direction (anticlockwise). The initial shape preferred orientation in the matrix is substantially

529   reduced with increasing strain. Figure 7 shows the evolution of grain shapes as best-fit ellipses,

530   using the ellipse shape averaging method reported in Wheeler (1984). The average aspect ratio

531   of the grains decreases from > 1.8 at the start of the experiment to a minimum of 1.12 at 110

532   time steps, before increasing again to 1.53 by the end of the run (Fig. 7a, which shows aspect

533   ratio evolution throughout the full model run; 215 time steps). The average orientation of the

534   long axis of grains rotates synthetically with increasing shear strain (Fig. 7b–d), i.e. clockwise,

535   but the change in average aspect ratio shows this is not simply due to rigid body rotation; grains

536   shorten in directions parallel to the shortening axis of the incremental strain ellipse, and

537   lengthen in directions parallel to the stretching axis of the incremental strain ellipse.

538
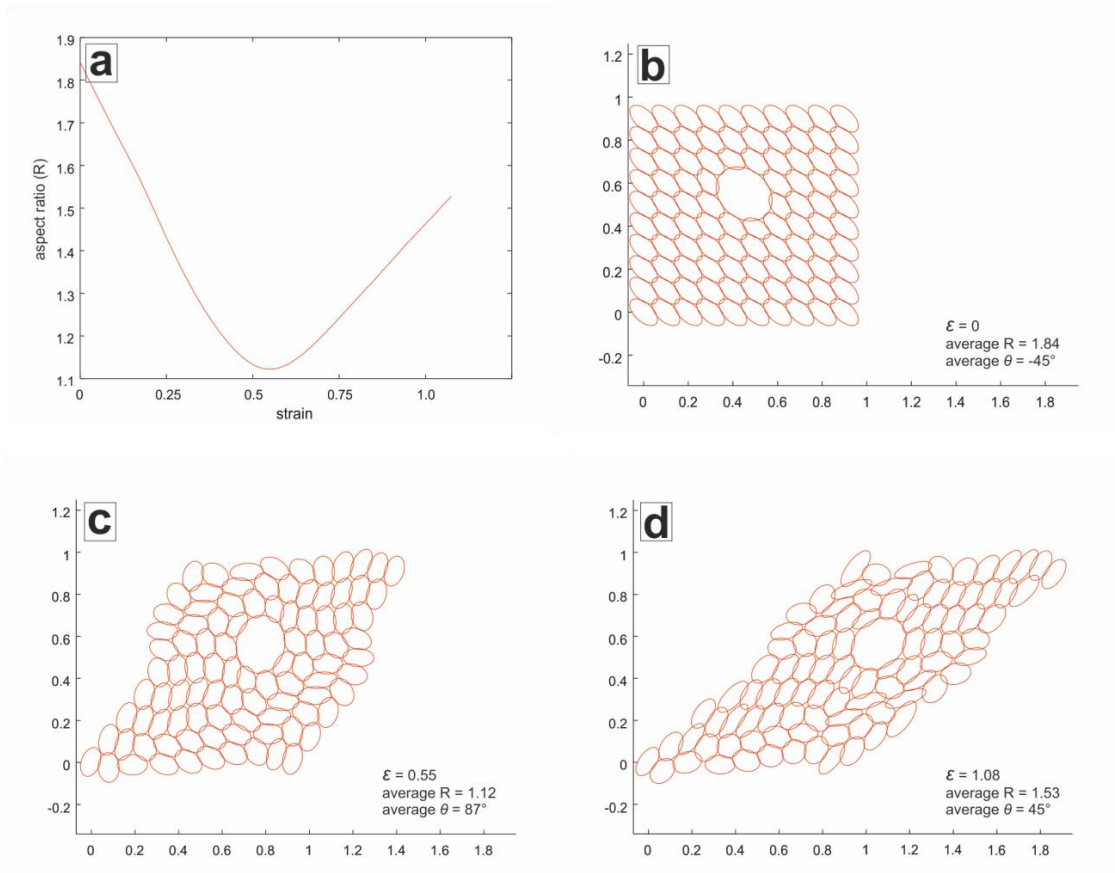

Figure 7 *a) Aspect ratio evolution during dextral simple shear. b) Best fit ellipses to grains in the starting net have an average aspect ratio (R) of 1.84, and the average angle of grain long axes to the horizontal is 45° clockwise. c) At a strain of 0.55 (half way through the model run) average aspect ratio of the best fit ellipses drops to 1.12, and on average long axes have rotated to almost vertical (87°). d) When the model run terminates, best fit ellipses have an average aspect ratio of 1.53, and long axes have continued to rotate to an average of 45° to the horizontal.*

546

Most grains retain their initial rotation direction for the duration of the experiment. Finite rotation over total strain is plotted for each grain in Figure 8a. Finite rotations are quite small until a strain of around 0.15, when grain rotations spread out rapidly in both rotation directions (Fig. 8a). Individual grain rotations subsequently decelerate with increasing strain, and the

551   mean of matrix grain rotations also flattens off, suggesting grain rotations are fairly stable (Fig.

552   8a–b). The standard deviation shows the spread in rotations continues to increase with strain

553   (Fig. 8b). In Figure 8c, the angular velocity of each grain is plotted against total strain. The

554   angular velocity plot shows a rapid increase in rotational velocity of individual grains in both

555   rotation directions between a strain of around 0.15 to a strain of around 0.2, after which rotation

556   velocities begin to fall. However, the mean angular velocity of the matrix grains (blue line in

557   Fig. 8c) remains fairly constant, indicating that the increase in angular velocities in each

558   direction is roughly the same, and suggesting that the angular velocities of matrix grains

559   directly impact their neighbours. The angular velocities of most grains flatten off at a strain of

560   around 0.4 and gradually evolve towards zero, again indicating evolution of the microstructure

561   towards a rotational steady state (Wheeler, 2009). Matrix grain rotations are clearly influenced

562   by the large grain, as they broadly follow the same pathway in both the finite rotation and

563   angular velocity plots (Figs. 8a and c). The differential stress evolution plot shows a constant

564   value until a strain of about 0.15 when it drops suddenly indicating a decrease in strength in

565   the net. This drop in strength correlates with the sharp increase in the angular velocity of the

566   large grain (and therefore all grains). As grain rotations stabilise, the differential stress curve

567   flattens, indicating the strength of the net has stabilised at a new, but lower, value.

568
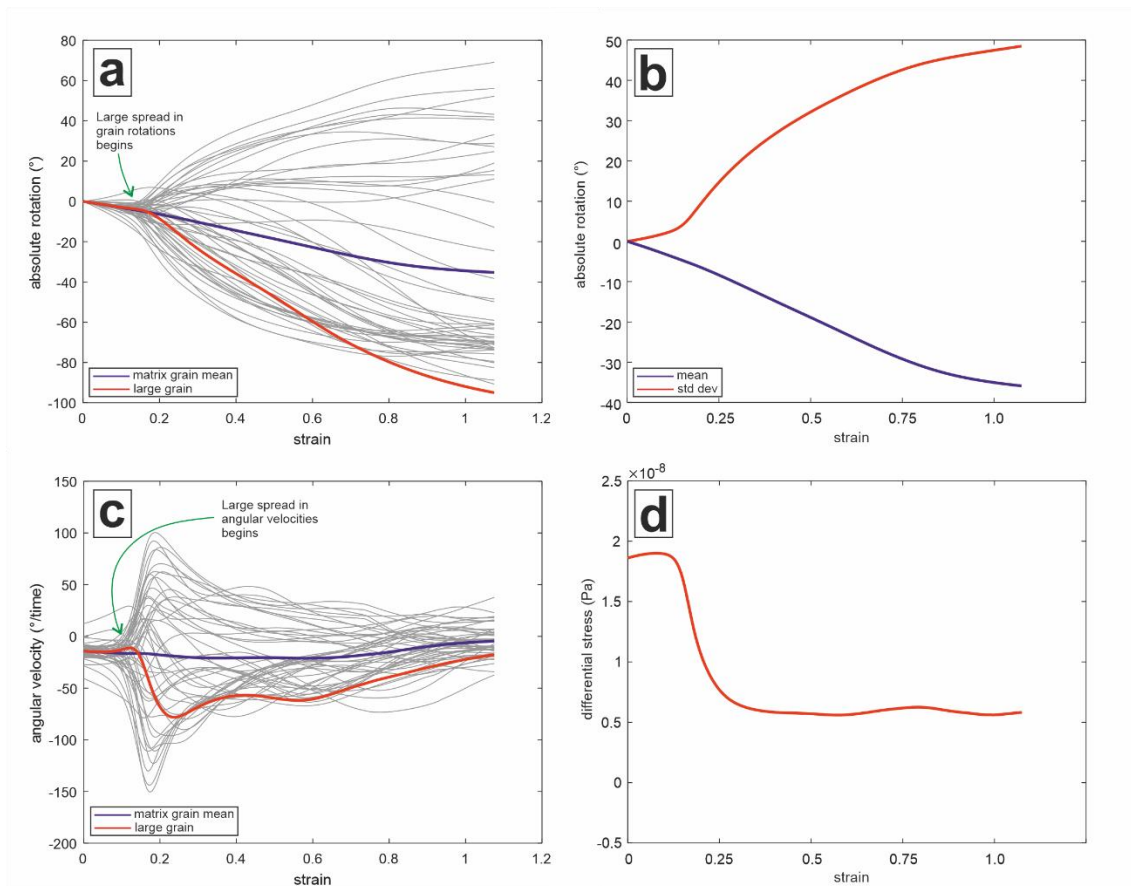

Figure 8 *a) Absolute rotation, in degrees, of each grain as a function of increasing strain in*

the dextral simple shear model (anticlockwise positive). The red line tracks rotation of the large

grain, and the blue line shows the mean rotation behaviour of matrix grains. b) Mean and

standard deviation of all grain rotations in the simple shear model. c) Angular velocity of all

grains as a function of strain in the simple shear model. The red line tracks the angular velocity

of the large grain, and the blue line shows the mean angular velocity of matrix grains. For an

animation of angular velocities throughout the entire evolution of the model, see the

Simple_ang_vel simulation in the supplementary materials. d) Evolution of differential stress

(i.e. strength evolution of the deforming microstructure) during the model run.

578

579   Figure 9 provides further insight into stress evolution in the simple shear model on the grain

580   scale. In contrast to the pure shear experiment, starting stresses are not close to zero (compare

581 Fig. 9a with Fig. 5a). Similar to the pure shear experiment, however, there is a row of matrix

582 grains parallel to the maximum shortening axis and in line with the large grain that

583 experience notably higher boundary stresses than their neighbours (Fig. 9a). In the animation

584 of this model run (Simple_stresses in the supplementary materials), this band of high stress

585 boundaries can be observed to rotate, as the axis of maximum shortening also rotates with

586 increasing strain. By a strain of approximately 0.25, the band of high stress boundaries

587 becomes obscured by stress on most other boundaries building to similar magnitudes (Fig.

588 9b). As strain proceeds, stress magnitudes on nearly all matrix boundaries drop substantially,

589 which appears to re-focus stress on boundaries associated with the large grain, so that at a

590 strain of around 0.5, a band of high stress boundaries reappears, in line with the large grain

591 and parallel to the axis of maximum shortening (Fig. 9c). Stress on other matrix grains then

592 builds again to obscure this band after a strain of around 0.9 (Fig. 9d), before the model

593 terminates.
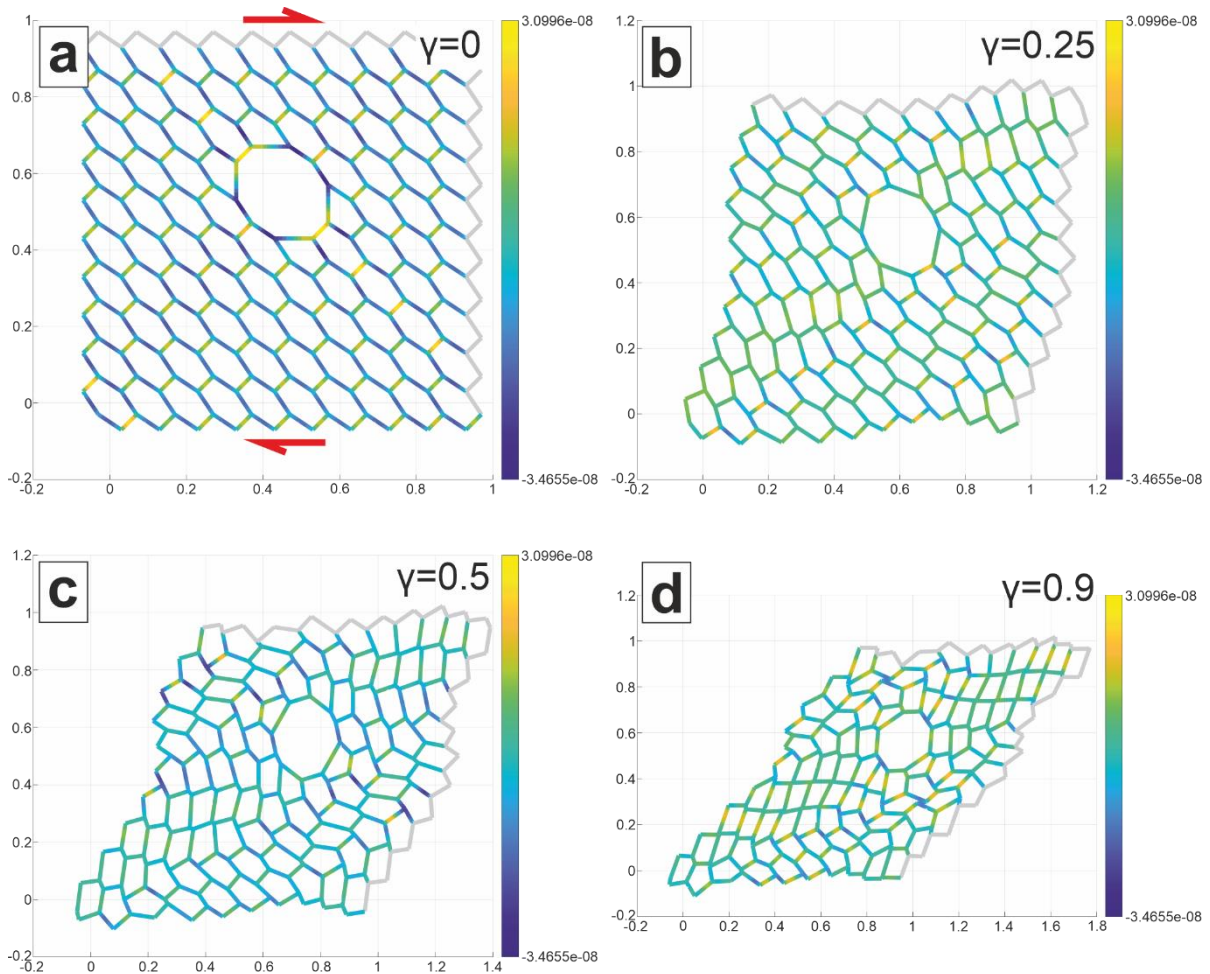

594

595 *Figure 9* *Grain boundary stresses at four time increments in the simple shear model run. a)*

596 *At the start of the simple shear run, grain boundaries experience noticeable stress. A row of*

597 *grains with larger boundary stresses runs top left to bottom right through the net due to the*

598 *presence of the large grain, similar to pure shear (compare Fig. 5b and see 3D simulation*

599 *Simple_stresses in the supplementary materials). b) As strain proceeds, stresses on all grain*

600 *boundaries evolve to similar magnitudes, similar to pure shear. c) After a drop in stress on*

601 *all boundaries, as also seen in pure shear, boundary stresses begin to build again on a row of*

602 *grains associated with the large grain (see also the 3D simulation Simple_stresses in the*

603 *supplementary materials). d) As strain proceeds, stresses on all boundaries evolve to similar*

604 *magnitudes again, suggesting the pattern in both pure and simple shear may be cyclical (see*

605 *the Simple_stresses simulation in the supplementary material for an animation of the full*

606 *model run).*

607 **5 Discussion**

608 *5.1 Grain rotations*

609 The rotation of large grains within a fine-grained matrix has received a considerable amount of

610 attention from the microstructural modelling community in the last few decades (e.g., Fay et

611 al., 2008; Griera et al., 2011; Griera et al., 2013; Johnson, 2009), primarily because

612 porphyroblast/clast rotation microstructures are routinely used in the interpretation of strain

613 histories. To date, models have tended to focus on deformation in the dislocation creep regime.

614 Because grain rotations are inherent to diffusion creep, which is promoted at finer grain sizes,

615 it is also important to assess the effects that diffusion creep in a fine-grained matrix may have

616 on the rotation of large grains. Grain rotations during diffusion creep occur in a very dynamic

617 environment, where rotations have a measurable impact on adjacent grains. In particular,

618 rotations of large grains can have significant effects on the surrounding matrix. Rotations of

619 large grains are generally assumed to be either synthetic or antithetic to shear (Griera et al.,

620 2013). The results presented here suggest a more complex picture, where the rotation direction

621 of the large grain can in fact change over time as the large and matrix grains interact (Fig. 4a),

622 which in turn can lead to significant changes in local stress distributions (Fig. 5) and an

623 associated drop in strength (Fig. 4d). This observation has significant implications for the

624 extrapolation of strain histories from microstructures. For example, metamorphic garnets are

625 commonly littered with inclusions whose distributions are interpreted as regional-scale shear

626 sense indicators. If local changes in the rotation direction of large grains can occur due to

627 interactions between large and matrix grains during pressure solution/diffusion creep,

628 relatively simple imposed strain paths could potentially give rise to microstructures that might

629 be interpreted as the product of vastly more complicated strain histories, e.g. a single

630 deformation phase may erroneously be interpreted as multiphase (Fossen et al., 2019). The

631 counter argument to this is that inclusion trails are often observed to be correlated between

632   different porphyroblasts on the outcrop to regional scale (Aerden, 1995; Aerden and Ruiz-

633   Fuentes, 2020; Fay et al., 2008; Johnson, 1990; Steinhardt, 1989), and if inclusion trail patterns

634   resulted from locally turbulent behaviour, it would be impossible for them to maintain

635   regionally consistent orientations. Further, it would be impossible for different age sets of

636   porphyroclasts to develop distinct inclusion trail sets with regionally-consistent orientations

637   (Aerden et al., 2020; Aerden and Ruiz-Fuentes, 2020). However, it is not always the case that

638   inclusion trails in a single sample have consistent orientations. For example, Johnson et al.,

639   (2006) analysed staurolite inclusion trails in low-pressure, high-temperature schists that formed

640   during the development of crenulation cleavage, finding a spread in inclusion trail orientations

641   of 40–75° that provided clear evidence for the large staurolite grains rotating relative to one

642   another and to the crenulation cleavage. More detailed modelling on the evolution of grain

643   rotations to very high strains, and their effects on stress distributions on the grain scale, would

644   give valuable insight into how finite strain microstructures should be interpreted. Of particular

645   use would be DiffForm models that included more than one large grain, so their relative

646   rotations could be analysed. At present, there are computational constraints on constructing

647   and running such starting geometries in DiffForm (see section 5.4.2).

648   In the current model runs, rotations of matrix grains are clearly influenced by the presence of

649   the large grain. In the pure shear model, the presence of the large grain appears to affect the

650   overall strength the microstructure by suppressing the rotations of certain grains, which results

651   in stress build-up on specific boundaries. The local distribution of stress in this case happens

652   to lead to an alignment of grain boundaries, which acts as a plane of weakness within the net.

653   The inference here is that a rock comprised of grains with a homogeneous grain size deforming

654   by diffusion creep may be stronger than those with greater diversity of grain size, because large

655   grains can act to focus stresses, and resultant microstructural modifications inherent in

656   diffusion creep, into specific areas. This can result in the development of mechanical

657   heterogeneities that weaken the bulk rock, and may lead to weak zones/decoupling of interfaces

658   around large grains similar to those previously modelled in the dislocation creep regime (Griera

659   et al., 2011).

660   *5.2 Preservation or formation of a CPO*

661   Shape preferred orientations (SPOs) have been observed to develop during diffusion creep (e.g.

662   Díaz Aspiroz et al., 2007; Getsinger and Hirth, 2014; Imon et al., 2004), and CPOs can develop

663   in tandem with an SPO. Furthermore, it has been shown that inherited CPOs can be retained

664   during diffusion creep deformation (Jiang et al., 2000; Wheeler, 2009). In the pure shear

665   experiment performed here, a CPO would not be expected to develop from a random initial

666   texture, as the rotations of all grains follow the same path, i.e. all grains largely rotate the same

667   amount, and in the same direction, so the initial random texture is preserved. However, if there

668   was an initial CPO in the matrix grains of such a rock, it would be largely preserved, albeit

669   weakened, by the diffusion creep deformation. A starting net with a more heterogeneous grain

670   size may evolve quite differently so further work is required in this area.

671   In the simple shear experiment, the story is more complex but follows the same trend; a rock

672   with no initial crystallographic alignment would not develop one during diffusion creep

673   deformation. However, if an initial CPO did exist, crystallographic alignment would also be

674   observed in the final geometry, but the original CPO would have been split into two smaller

675   CPO 'domains' – one whose grains share an orientation because they rotated in the same

676   direction as the large grain, and another whose grains share a different orientation, related to

677   rotation directions that are antithetic to the large grain rotation direction, but share the same

678   direction and velocity as one another, so any initial shared orientation is preserved during

679   rotation.

680   *5.3 Strength evolution*

681   Grain rotations have effects beyond those on the rock's texture. Microstructure influences the

682   physical properties of deforming crystalline materials, and the experimental results presented

683   here clearly indicate that the strength of a rock (or other crystalline material) deforming by

684   diffusion creep can be influenced by grain rotations. When rotations are large and fast, the

685   microstructure can be interpreted to 'destabilise' (i.e. transiently evolve away from overall

686   steady-state behaviour; Figs. 4c and 8c), with an associated drop in strength (Figs. 4d and 8d),

687   in both pure and simple shear. This transient behaviour appears to be controlled by how rapid

688   the rotation of the large grain is within the fine-grained matrix. Again, it is the heterogeneity

689   in the microstructure that causes these effects.

690   The presence of a large insoluble grain is also shown to affect the local distribution of grain

691   boundary stresses, with those grains in closest proximity to and in line with the large grain

692   parallel to the axis of maximum shortening experiencing a greater magnitude and more rapid

693   build-up of stress than other matrix grains (Figs. 5 and 9). In pure shear, the change in rotation

694   direction appears to have a profound effect on the way stresses are distributed on boundaries

695   throughout the model, with high stresses rapidly redistributed away from the single row of

696   grains to all other boundaries (Fig. 5). A similar pattern of stress redistribution behaviour

697   occurs in the simple shear run, but the sequence of i) a build-up of stresses close to the large

698   grain before ii) redistribution onto matrix grains, followed by iii) a drop in stress on all

699   boundaries, appears to at least begin a second cycle. This can best be seen in the Pure_stresses

700   and Simple_stresses animations in the supplementary information. The suggestion of such

701   cyclical behaviour warrants further investigation to higher strains.

702   The low stress values shown in Figures 4d and 8d are a result of legacy values for some

703   coefficients used during model development: in section 2 we showed that for equivalent size

704   spheres $\eta = 1.461$ x 10^{-8} Pa.s. For simple shear (Figs.6–9), the shear strain rate is $\dot{\gamma} = 0.5$ s^{-1},

705   so the equivalent differential stress (twice the shear stress) is 1.5 x 10^{-8} Pa. This value is of a

706   similar order of magnitude to the starting value of differential stress in the model, which is 1.9

707   x 10^{-8} Pa. The theoretical value is slightly lower than the modelled value because elongate

708   grains are stronger than equant grains of equivalent area; e.g. Elliott (1973) showed that at

709   constant stress, grain elongation results in a decrease in strain rate. Moreover, Coble's (1963)

710   derivation is for notional spherical grains. These provide diffusion pathways in all three

711   dimensions and so strength is lower than for "two-dimensional" grains which in effect have

712   infinite length in the third dimension.

713   The initial strength of the net in pure shear was close to zero (Figs. 4d & 5a). Wheeler (2010)

714   discussed anisotropic rheology during diffusion creep, with particular reference to a periodic

715   microstructure constructed of a single irregular hexagonal grain shape. The results of Wheeler

716   (2010) showed that anisotropy occurred in two orthogonal strong directions, and two

717   orthogonal weak directions that lie at 45° to the strong directions. The model runs in this study

718   were set up so that grain boundaries had zero viscosity, and, under these conditions, the weak

719   directions have low strength. The large grain was expected to have some effect on the strength

720   of the starting net, but it seems to have been minor. The initial very low strength of this net is

721   explained by the fact that the elongate hexagons which comprised the initial microstructure

722   were oriented in such a way that the direction of imposed pure shear happened to be aligned

723   with the weak directions. As finite grain rotations occurred, the strength of the microstructure

724   increased as the weak directions rotated away from parallelism with the imposed shear stress

725   (Fig. 4d).

726   A periodic microstructure can create spurious results in models of diffusion creep, as discussed

727   below in section 5.4. In pure shear, alignment of matrix grain boundaries is considered to lead

728   to the observed drop in strength. Could the periodicity in the starting net be the reason for

729   boundary alignment and associated strength drop? This is not thought to be the case, as sliding

730   surfaces nearly always develop due to boundary alignment in starting nets with heterogeneous

731   grain geometry during diffusion creep, and affect the strength of the nets in the same way as

732   observed here (Wheeler, 2009, and unpublished models). Thus, boundary alignment is simply

733   a natural product of diffusion creep deformation. The results of both the pure and simple shear

734   simulations show that the presence of large grains will influence where within the

735   microstructure such boundary alignment (and therefore sample weakening) will occur.

5.4 Model limitations and future work

736

5.4.1 Effect of a periodic matrix on microstructure evolution

737

738   Although many natural rocks do exhibit an SPO, the geometry of the matrix grains in the start

739   net used here is somewhat artificial. Such periodicity of grain shape can cause problems in

740   diffusion creep modelling because the neighbour switches that occur as a natural product of

741   diffusion-accommodated grain boundary sliding (Spingarn and Nix, 1978) all occur at the same

742   time throughout the microstructure. Such synchronised grain switching is unrealistic and thus

743   will produce a somewhat simplified deformation behaviour. In addition, the grain shape

744   anisotropy in our starting net is orientated at 45° to the maximum shortening axis of the

745   instantaneous strain ellipse in both the pure shear and simple shear model runs. As discussed

746   in section 5.3, Wheeler (2010) showed that irregular hexagons develop an anisotropic rheology

747   in diffusion creep, so that a polycrystal made of repeating hexagons exhibits an overall

748   anisotropic rheology in DiffForm models (see Fig. 4 of Wheeler, 2010. The effect of this

749   anisotropy is reflected in the stress evolution of the pure shear and simple shear models

750   presented here (Figs. 4d and 8d). Work in progress suggests there is a rigorous mathematical

751   basis to expect anisotropic rheology will also develop in more irregular microstructures, with

752   initial results comparable to those presented in Figure 4 of Wheeler (2010). Therefore, we do

753   not expect the initial shape anisotropy of our starting nets to have spuriously influenced

754   evolution of the microstructure.

755   The advantage of a mostly-periodic matrix is that it is easy to identify differences in the

756   behaviour of matrix grains that are a result of (in this case) the presence of a large grain. Despite

757   the differences between the simplified starting net and natural microstructures, such modelling

758   is an important first step in understanding how microstructural evolution proceeds in crystalline

759   materials with grain size heterogeneity during diffusion creep. Further work on more realistic,

760   heterogeneous starting geometries is necessary to elucidate the effects of large grains on stress,

761   grain rotations, and other aspects of microstructural evolution in real rocks.

762   *5.4.2 Relative size of large grain and matrix grains*

763   In the current model microstructure, the second phase grain is an order of magnitude larger

764   than the matrix grains. Porphyroblasts in natural rocks have cross-sectional areas that are

765   commonly 3 to 4 orders of magnitude larger than matrix grains (e.g. Vernon, 2018), meaning

766   many more matrix grains lie adjacent to large grains. At present, this difference in grain size

767   cannot be modelled in DiffForm due to issues with boundary switching at key nodes that

768   compose grain boundaries lining the edge of the model net. When a finer matrix grain size is

769   used, greater issues with boundary switching lead to model runs terminating at low strain,

770   before much microstructural change has occurred. Similarly, it would be insightful to compare

771   the behaviour of more than one large grain within a single experiment, but this cannot currently

772   be achieved due to constraints on the smallest workable matrix grain size. Solving this issue is

773   an important next step in the future development of the DiffForm modelling suite.

774   We speculate that an increased difference in relative size of large and matrix grains is unlikely

775   to substantially change the rotational behaviour of large grains from that observed here. A finer

776   grain size would make the matrix weaker (due to grain boundary diffusion creep having a grain

777   size exponent of 3 in Eq. 2; Poirier, 1985), which may decrease the rotational stability of the

778   large grain. However, the ductility contrast between the two phases is already defined to be

779   (almost) infinite in the model, so the relative weakness of the matrix with respect to the large

780 grain would not noticeably change. One instance where a greater number of fine grains lining

781 a porphyroblast boundary could potentially arrest rotation behaviour is if those fine grains all

782 rotated in the opposite direction to their neighbours, as observed in the simple shear model, in

783 such a way that the resulting sum of traction on all large grain boundary segments was equal

784 to zero. However, in a matrix where grain shapes show greater heterogeneity, as observed in

785 nature, it is difficult to see this scenario occurring.

786 **6 Conclusions**

787 During the microstructural evolution of a fine-grained matrix undergoing diffusion creep:

788 1) Rotations of matrix grains are strongly influenced by rotation of large grains, especially
789 matrix grains that lie adjacent to large grains.

790 2) The rotation direction of a large grain does not have to be simply either synthetic or
791 antithetic; rotation directions can change due to interactions with the matrix, and the
792 overall evolution of grain rotations in a rock undergoing diffusion creep is complex.

793 3) The presence of large grains is unlikely to influence formation of a CPO. However, a
794 pre-existing CPO can be largely preserved, and depending on the shear geometry may
795 be split into smaller domains due to the influence that large grain rotation has on matrix
796 grains.

797 4) Large grains create stress heterogeneities that focus the effects of diffusion creep. This
798 can influence how and where grain boundaries align within a microstructure, which can
799 lead to a profound drop in strength of a material.

800 5) The local distribution of matrix grain boundary stresses is clearly influenced by
801 proximity to large second phase grains. Stresses are greater on boundaries oriented
802 favourably to the axis of maximum shortening. The model results suggest some kind of
803 cyclical transfer of stress into different parts of the matrix may occur during diffusion
804 creep, which is influenced by switches in the rotation direction of large grains.

805   6) An increase in the velocity of a rotating large grain can lead to the angular velocities of

806   matrix grain rotations transiently evolving away from steady-state, which results in a

807   significant drop in the strength of a material deforming by diffusion creep. However,

808   individual grain rotations can return to a steady-state, which re-stabilises the strength

809   of the material, but at a value lower than the starting strength.
