Abstract

Background and aims: Root growth alters the rhizosphere thereby affecting root uptake of water and nutrients. However, the influence of abiotic stress on this process is poorly understood. In this study we investigated the effects of water and salinity stresses (both in isolation and combined) on maize (*Zea mays* L.).

Methods: Seedlings were grown in pots packed with a loamy sand soil for two weeks and then subjected to water and salinity stresses, together with an unstressed control. After an additional two weeks, plants were removed from the pots and the soil aggregates adhering to the roots were collected and scanned using X-ray Computed Tomography. The ability of the aggregates to conduct water was calculated from pore-scale simulation of water flow using the lattice Boltzmann method.

Results: It was found that both water and salinity stresses reduced the permeability of the rhizospheric aggregates, although the reduction under salinity stress was more significant than under water stress. Combining water and salinity stresses reduced the permeability of the rhizosphere by one order in magnitude compared to the unstressed rhizosphere.

Conclusions: Abiotic stresses work with root-induced activity to reshape the rhizosphere. As water and nutrients need to pass through the rhizosphere before being taken up by roots, understanding such rhizosphere changes has an important implication in plant acquisition of soil resources.

Key words: *Rhizospheric permeability; pore-scale modelling; abiotic stress; tortuosity.*

1. Introduction

The rhizosphere is the small volume of soil impacting and being impacted on by plant roots. It is the most active zone in terrestrial ecosystem (Gregory 2006). The large quantity of rhizodeposits secreted by roots, along with the imbalanced uptake of cations and anions by roots, makes the rhizosphere differ markedly from the bulk soil both physically and biochemically (Hinsinger et al. 2005). Early experiments showed that root growth led to a densification of the rhizosphere (Dexter 1987), while recent studies found that root-mediated physical and biological processes could also increase the rhizosphere porosity through enhancing aggregation (Helliwell et al. 2019; Rabbi et al. 2018).

The change in physical properties of the rhizosphere is a result of the interplay of a multitude of biotic and abiotic processes (Hinsinger et al. 2009). Physically, root growth radically deforms adjacent soil resulting in a compression of the surrounding pore space. In contrast, mucilage and extracellular polysaccharides (EPS) exuded by roots and microorganisms have been shown to boost soil aggregation and increase the number of large pores relevant to water and nutrient flow (Alami et al. 2000). In addition to restructuring the rhizosphere, the mucilage and EPS also alter the surface tension and viscosity of soil water (Ahmed et al. 2018; Carminati 2012; 2013; Hallett et al. 2003; Read et al. 2003; Read and Gregory 1997; Zarebanadkouki et al. 2016), rendering the rhizosphere either hydrophilic or hydrophobic depending on its moisture content (Carminati et al. 2010; Carminati et al. 2011). Such a dynamic change in physical properties of the rhizosphere has a paramount impact on root uptake of water and nutrients (Kroener et al. 2014; Schwartz et al. 2016).

Most research on change in the rhizosphere hydraulic properties has focused on water retention, whereas there is a paucity of studies on alteration of the rhizospheric hydraulic conductivity as directly measuring water flow in the rhizosphere is very difficult even using modern tomography (Huang et al. 2015; Ren et al. 2015) and tracer- based technologies

62 (Totzke et al. 2017). As a result, indirect methods have been used as an approximation. For

63 example, Zarebanadkouki et al. (2016) calculated the permeability of a lupin rhizosphere

64 based on radiographic images acquired using neutron tomography, and Rabbi et al (2018)

65 calculated the permeability of a chickpea rhizosphere through pore-scale simulation based on

66 X-ray CT images. Similar methods had also been used by others to calculate the unsaturated

67 hydraulic conductivity of the rhizosphere (Daly et al. 2015; Tracy et al. 2015). These indirect

68 methods provided some insight into how roots modulate their rhizosphere to facilitate water

69 uptake, but they need to make assumptions about water flow in the void space which are

70 difficult to justify experimentally. For example, the pore-scale simulations need to know the

71 water velocity at the water-solid and water-air interfaces. While the water-solid interface

72 could be assumed to be a non-slip boundary in hydrophilic soil where the water velocity is

73 zero (Rabbi et al. 2018), the water-air interface for unsaturated flow is difficult to decide *a*

74 *priori* (Tracy et al. 2015; Zhang et al. 2016c). Research on using neutron imaging to inversely

75 estimate the hydraulic conductivity of the rhizosphere has shown potential, but it required

76 information on hydraulic conductance of the roots which is difficult to measure *in vivo*

77 (Zarebanadkouki et al. 2016). Also, because neutrons are very sensitive to water, the

78 application of neuron tomography to soil-root interactions was limited to 2D radiographic

79 images (Carminati et al. 2010).

80   The putative role of the rhizosphere in regulating water uptake by changing its hydraulic

81 properties has been well established (Bengough 2012), but the impact of abiotic stresses on

82 this change is an issue that remains elusive. This paper aims to study this using maize in a

83 pot-based microcosm. Two weeks after seedling emergence, healthy plants were subjected to

84 water and salinity stresses, both in isolation and combination, of the kind typically

85 encountered in important maize-growing aridic regions in the world. After an additional two

86 weeks, we extracted the roots out to harvest the aggregates adhering to the roots and scanned

them using X-ray CT. The porosity, pore-size distribution of all aggregates were estimated

from the segmented images, while their permeability and tortuosity were calculated from

pore-scale simulations of water flow and solute diffusion in the void space. Comparisons

were made with aggregates taken from the unstressed control.

2. Materials and methods

2.1. Plant and soil

Maize (*Zea mays* L. var. Delprim) was grown in pots (20 cm high with an internal

diameter of 15 cm) packed with a loamy sand soil collected from Woburn at Bedfordshire in

the UK at a bulk density of 1.45g cm^{-3}. The soil was an Arenosol (FAO soil classification)

comprising 80% sand, 12% silt and 8% clay (Nicholson et al. 2018). Prior to packing, the soil

was firstly air-dried and then sieved (4 mm). The soil moisture in all pots was adjusted to

24% (weight content) before sowing the seeds at a depth of 5cm. The pots were then placed

in a greenhouse at 25°C under 14h photoperiod (06:00-20:00) and irrigated with Hoagland

nutrient solution at 3, 7 and 11 days after the seedling emergence respectively (three days

after sowing). After the seedlings were established (two weeks after their emergence), we

subjected some plants to water stress and salinity stress, in both isolation and combination,

whilst a subset of the plants remained as unstressed controls (CK). We therefore created four

treatments: CK (unstressed), water-stressed, salinity-stressed and water + salinity-stressed.

Soil moisture in each pot was monitored using a WET-2 sensor connected to a HH2 meter

(Delta-T120 Devices, UK). The water stress and salinity were to mimic what the maize

grown in northern China often meets (Zhao et al. 2019). The CK treatment added 190 ml of

Hoagland solution to the pot whenever the soil moisture measured using the sensor dropped

to 60% of the field capacity (equivalent to 28%, weight content) and the water-stress

irrigation treatment added 90 ml of Hoagland solution to the pots at the same time as the CK

treatment. For the salinity stress associated with each irrigation treatment, 50mM of NaCl

112 was added to the Hoagland solution in the first irrigation event, 14 days after the seedling

113 emergence. Two weeks after the stresses started, we upturned each pot and gently removed

114 the soil and roots out. The loose soil was shaken off the roots first and we then manually

115 removed three aggregates adhering to different roots from each treatment. As a comparison

116 we also took aggregates from an unplanted pot. All aggregates were geometrically irregular

117 and their size was approximately in the range of 2-5 mm.

118 *2.2. Image acquisition and processing*

119 All aggregate samples were scanned using a Phoenix Nanotom X-ray CT scanner at the

120 Hounsfield Facility at the University of Nottingham. The samples were loaded in a plastic

121 tube which was mounted on the manipulation stage in the chamber of the scanner. The

122 samples were scanned using an electron acceleration energy of 85 keV and a current of 100

123 μA at a spatial resolution of 4μm, with each sample taking approximately 30 mins to scan.

124 Each scan consisted of the collection of 3600 images with a detector timing of 500 ms. The

125 raw images were constructed using the software phoenix datos|x (Waygate Technologies) and

126 they were then saved as a stack comprising 16-bit greyscale 2D slices.

127 The images were processed with Image J (University of Wisconsin-Madison). We first

128 cropped the irregular images to a cube or cuboid prior to enhancing their contrast to 0.3% and

129 converting the16-bit images to 8-bit images. The noise in the image was reduced before

130 segmentation. A voxel was defined as a noisy voxel if its attenuation number differed

131 markedly from those of its immediate adjacent voxels, and we replaced it by the average

132 attenuation number of the adjacent voxels. The image was segmented using a threshold

133 calculated from the IJ-IsoData algorithm in Image J.

134 Pore-size distribution in each image was calculated using the Plug-in CT-image Analysis

135 & Manipulation (SCAMP) in Image J (Houston et al. 2017). To verify the method, we

136 recalculated the pore-size distribution using Bone J finding the difference between the two

137 was less than 5%. In what follows we only present the results obtained from SCAMP. Since

138 all noisy voxels had been removed, only pores > 4μm were accounted in pore size

139 calculation. We expressed pore-size distribution as relative volume of all pores with the same

140 diameters rather than their absolute volume (Vogel and Kretzschmar 1996; Vogel et al.

141 2010).

142   Water and solute can only move through the pores that are hydraulically connected, and

143 we thus removed the isolated pores using the method we previously proposed (Zhang et al.

144 2016b) before simulating water flow and solute diffusion. In what follows the porosity refers

145 to the relative volume of all hydraulically connected pores.

146 *2.3. Permeability*

147   The permeability of each aggregate was calculated from pore-scale simulation of water

148 flow using the lattice Boltzmann (LB) method we previously developed (Li et al. 2018a;

149 Zhang et al. 2016b; Zhang et al. 2005; Zhang and Lv 2007) as given in the appendix. Water

150 flow through the pore space was driven by an externally imposed pressure gradient. The flow

151 was simulated to steady state when the absolute relative difference between the velocity in all

152 voxels simulated at two times spanned 100 time steps was less than 10^{-7}. At steady state, the

153 water velocity and water pressure in the voxels were volumetrically averaged over each

154 section normal to the pressure gradient direction. The permeability of each aggregate was

155 calculated as follows assuming that the volumetric average flow rate (q) and volumetric

156 average pressure (P) follows the Darcy's law:

157 $$q = -\frac{k}{u}\nabla P,$$ (1)

158 where k is the permeability and u is the dynamic viscosity of the water. The permeability of

159 each aggregate was therefore be calculated as follows from the simulated results:

160 $$k = \frac{\mu q L}{P_0 - P_1},$$ (2)

6

161 where L is the length of the image in the direction over which the external pressure gradient

162 was imposed, and P_0 and P_1 ($P_0 > P_1$) were the two constant pressures imposed on the two

163 opposite sides of the image to drive the water to flow. For each cuboid image, we calculated

164 its permeability in three directions. When imposing the pressure gradient in the z direction to

165 calculate the permeability in this direction, q was calculated from

166
$$q = \frac{1}{N} \sum_{i=1}^{N} u_z \left(x_i, y_i, z_i \right), \tag{3}$$

167 where N is the number of all voxels in the image, $u_z(x_i, y_i, z_i)$ is the water velocity

168 component at voxel centred on (x_i, y_i, z_i) and in the z direction. Permeability in other two

169 directions was calculated similarly.

170 Once the permeability was known, its associated hydraulic conductivity K can be

171 calculated from $K = kg / \upsilon_w$ where g is the gravitational acceleration and υ_w is the kinematic

172 viscosity of the water. Since water viscosity is not a constant but varies with its chemical

173 composition and temperature, in what follows we will use permeability rather than converting

174 it to hydraulic conductivity.

175 *2.4. Tortuosity*

176 The permeability of a soil depends not only on its porosity but also on how the pores of

177 different sizes are spatially connected. We used tortuosity to represent the change in pore

178 connectedness in each aggregate and calculated it as the ratio between the effective diffusion

179 coefficient of the aggregate for a solute and the bulk diffusion coefficient of the solute in free

180 water. The effective diffusion coefficient was calculated using the lattice Boltzmann model

181 we developed previously for pore-scale simulation as detailed in the appendix (Hu et al.

182 2014; Li et al. 2018b; Zhang et al. 2016a). As for the permeability, for each cuboid image we

183 also calculated its tortuosity in the three directions.

184 **2.5. Statistical analysis**

185   Statistical comparison of porosity, permeability, tortuosity and pore-size distribution

186   between the treatments was performed using the software Matlab. The difference in the mean

187   between the treatments was assessed by analysis of variance (ANOVA) and post-hoc

188   pairwise comparisons of the treatment-means were performed using the Duncan's multiple

189   range test with the difference considered significant at $p < 0.05$. The difference in pore-size

190   distribution between the treatments was calculated using the Kolmogorov-Smimov test.

191   **3. Results**

192   Figure 1 shows four pairs of 3D greyscale images and their associated segmentations

193   with one pair illustratively representing one treatment. Figure 2 compares a 2D slice and its

194   segmentation. Visual comparison of the greyscale and segmented images in both 2D and 3D

195   revealed that the segmentation method correctly captured the pore geometries.

196   Figure 3 compares the average pore-size distributions. In general, abiotic stress reduced

197   the relative volume of large pores and increased the relative volume of small pores, especially

198   for aggregates subjected to the combined salinity and water stress. Pore-size distributions for

199   aggregates subjected to water and salinity stress in isolation are comparable and the

200   Kolmogorov-Smimov test did not find significant difference between CK and all treatments.

201   Because of beamtime limitation we only scanned one sample taken from the unplanted pot

202   and thus excluded it in statistical analysis hereafter, and its porosity and permeability are

203   shown the permeability section.

204   Figure 4a compares the porosity of the aggregates under different treatments. Abiotic

205   stress led to a reduction in aggregate porosity, especially for the combined water and salinity

206   stress which reduced the porosity significantly (p<0.05) from 0.246 in the CK to 0.167.

207   Difference between the three stress treatments, as well as the difference between the CK and

208   the treatments with the stresses working in isolation, were not significant.

209   The tortuosity for different treatments was compared in Figure 4b. Abiotic stress resulted

210   in a significant increase in tortuosity, compared with CK ($p<0.05$). There was no significant

211   difference between the three stress treatments.

212   The permeability calculated for the three orthogonal directions in each aggregate differed

213   for some aggregates. As permeability is a sensor, for the pressure gradient imposed in each

214   direction we calculated both the diagonal and the off-diagonal permeability components and

215   found that for most aggregates, the two off-diagonal permeability components were at least

216   one order in magnitude smaller than the diagonal permeability components. In the analysis,

217   we thus used the average of the three main permeability components in each aggregate to

218   compare the treatments. Figure 4c shows the permeability of the aggregates under different

219   treatments. It was manifested that both stresses reduced the rhizospheric permeability

220   significantly ($p<0.05$) either working alone or in combination. Compared with the CK, water

221   stress reduced the average permeability by approximately 60% and salinity stress by 80%,

222   while combining water and salinity stress reduced the permeability by nearly 90% from 4.32

223   μm^2 to 0.49 μm^2. The reduction in permeability under stress is partly due to the decrease in

224   porosity, and the relationship between the permeability and the porosity for all treatments

225   appeared to follow a power law with an exponent of 4.42 as shown in Figure 5. However, the

226   deviation from the power law indicates that the change in porosity was important but not the

227   only reason.

228   **4. Discussion**

229   The permeability and tortuosity calculated from pore-scale simulations for aggregates not

230   subjected to abiotic stress differed significantly from those subjected to water and salinity

231   stresses, although the differences between the treatments with the stresses working alone or in

232   combination were not statistically significant (Figures 4b, c). As we thoroughly sieved and

233   mixed the soil before packing it into the pots, the aggregates formed on the root surfaces were

234 likely the consequence of roots and root-mediated processes. As such, the variation between

235 their permeability and tortuosity was due to the impact of the treatments rather than spatial

236 heterogeneity. This was also corroborated by the porosity, for which we found significant

237 difference ($p<0.05$) only between the CK and the treatment with combined water and salinity

238 stresses, while the differences between the CK and other treatments were not significant

239 (Figure 4a). These results alluded that the change in permeability and tortuosity was not

240 solely caused by porosity change, and that the pore structure formed by biotic activities in the

241 aggregates, such as root hairs and fungus, might also play an important role. These, along

242 with other processes, made the aggregates in the vicinity of the rhizosphere respond

243 differently to the abiotic stresses (Crawford et al. 2012), although it was impossible to discern

244 the relative dominance of one over another.

245 Compared to the CK, salinity working in isolation or combined with water stress reduced

246 the permeability and tortuosity of the aggregates at $p<0.05$ significant level (Figures 4b, c).

247 NaCl was added to deliberately salinize the soil and the Na could have dispersed the clay

248 particles and consequently weakened the aggregation in both the rhizosphere and bulk soil.

249 This could be one reason underlying the reduced porosity and permeability of the rhizosphere

250 under salinity stress, but this does not appear to be the only one as water stress also reduced

251 porosity as much as the salinity did (Figure 4a).

252 Soil permeability depends not only on porosity but also on how pores of different sizes

253 are spatially organized. The tortuosity of aggregates under different treatments showed that

254 salinity rendered the soil more tortuous than water stress, making the aggregate more difficult

255 for water and solute to move (Figures 4b). Although salinity and water stress changed intra-

256 aggregates pores and their ability to transport water and solute, the change in permeability

257 with porosity for samples taken from all treatments appears to follow the common

258 relationship ($R^2=0.65$) as shown in Figure 5, manifesting the importance of porosity.

However, the deviation from the power law implies that the shape and spatial organization of the pores also played an important role.

Reduction in rhizosphere porosity and its ability to conduct water and solute due to water and salinity stresses would restrict root uptake of water and acquisition of dissolved solutes by the plant. Apparently, we do not know if this is a physiological response of the plant as a self-defence mechanism to reduce transpiration (saving water under water stress) and salt uptake (ameliorating salt toxicity) or purely a passive soil physical process without active involvement of the plant.

Visual observation of the root architectures revealed that the abiotic stresses curtailed root ramifying and made the roots thinner than those not under stress (Figure 6). Radial expansion of roots locally compacts the soil and thus thick roots should mechanically densify the rhizosphere more than the thin roots. However, our data do not support this and in contrast, the opposite appears to be true indicating that other mechanisms might have played a role in structural and hydraulic change in the rhizosphere under water and salinity stresses.

Maize is known to exude a large amount of mucilage into the soil providing C to support a diverse microbial community. This process can bind soil particles together and enhance aggregation in the rhizosphere (Benard et al. 2019). Aggregates bound by mucilage are quite stable even after desiccation (Benard et al. 2019); such aggregations could create pores detectable by X-ray imaging at resolution of 4μm. For example, the experimental study of Benard et al (2019) showed that amending soil with maize mucilage increased soil porosity by 10% but reduced the hydraulic conductivity because of the increase in water viscosity. We speculated that the abiotic stress might alter mucilage secretion and change soil aggregation and the intra-aggregate structure as a result. We used permeability rather than hydraulic conductivity to describe the ability of the aggregates to conduct fluid as we do not know to what extent the abiotic stresses and root-mediated processes had altered the water viscosity.

284 In addition to mucilage, the difference in root hair proliferation under different treatments

285 could be another mechanism underlying the change in porosity and permeability as affected

286 by abiotic stresses (Rabbi et al. 2018).

287   The enhanced aggregation by roots and their associated abiotic and biotic activities also

288 create large pores between the aggregates. Due to technical limitations, it was not possible to

289 scan the entire pots (20 cm high and 15 cm in diameter) at a resolution high enough to

290 identify the inter-aggregate pores. Therefore, our results on the impact of abiotic stresses on

291 soil structure were limited to the aggregates adhering to the roots rather than the alteration in

292 properties of the whole soil that includes both inter-aggregate and intra-aggregate features.

293 Also, we repacked soil into pots and conducted the experiments in a controlled environment.

294 This limited the space for roots to grow and did not capture the physical and biochemical

295 heterogeneity of the soil. Therefore, in is prudent not extrapolate our findings to those of

296 maize growing in field conditions. Notwithstanding these, our results do shed some light on

297 the role of abiotic stresses in mediating root-soil interactions and provide a way in which we

298 may improve our mechanistic understanding of the impact of real-world abiotic stresses on

299 crop growth.

300 **5. Conclusions**

301   This paper studied the impact of abiotic stresses on structural change in the rhizosphere

302 of maize and its consequence for the rhizospheric permeability and tortuosity using X-ray CT

303 and pore-scale simulations. The results showed that compared to an unstressed control, water

304 stress reduced the soil permeability by approximately 60% and the salinity stress reduced this

305 by 80% when working in isolation, while the two stresses in combination reduced the soil

306 permeability by 90%. Since water and nutrients need to pass through the rhizosphere before

307 being taken up by roots, change in hydraulic properties in the rhizosphere has important

308 implications for unravelling how roots respond to abiotic stress. Given the increased interest

309 in improving crop productivity by manipulating their root traits, understanding the changes in

310 hydraulic properties of the rhizosphere in response to abiotic stresses is critical. Since the

311 rhizosphere is only a few millimetres around the root and directly measuring its hydraulic

312 conductivity is difficult technically, combining pore-scale simulation and X-ray CT, as

313 described in this paper, could help to bridge this gap.

314 **Appendix A**

315 Water flow and solute diffusion through the void space of the segmented images were

316 both simulated by the following lattice Boltzmann model (d'Humieres et al. 2002):

317 $$f_i\left(\boldsymbol{x}+\delta t\boldsymbol{e}_i,t+\delta t\right)=f_i\left(\boldsymbol{x},t\right)+M^{-1}SM\left[f_i^{eq}\left(\boldsymbol{x},t\right)-f_i\left(\boldsymbol{x},t\right)\right], \tag{A1}$$

318 where $f_i\left(\boldsymbol{x},t\right)$ is the particle distribution function at location $\boldsymbol{x}$ and time t moving at lattice

319 velocity $\boldsymbol{e}_i$, δx is the size of the image voxels, δt is a time step, $f_i^{eq}\left(\boldsymbol{x},t\right)$ is the equilibrium

320 distribution function, M is a transform matrix and S is the collision matrix. The models for

321 water flow and solute transport differed only in their equilibrium distribution functions, both

322 involving a collision step and a streaming step to advance a time step. In each model, the

323 collision was calcculed as $m=SM\left[f_i^{eq}\left(\boldsymbol{x},t\right)-f_i\left(\boldsymbol{x},t\right)\right]$ first and m was then then transformed

324 back to particle distribution functions by $M^{-1}m$. In both models, we used the D3Q19 lattice in

325 which the particles move in 19 directions with velocities: $\left(0,\ 0,\ 0\right)$, $\left(\pm\delta x/\delta t,\ \pm\delta x/\delta t,\ 0\right)$,

326 $\left(0,\ \pm\delta x/\delta t,\ \pm\delta x/\delta t\right)$, $\left(\pm\delta x/\delta t,\ 0,\ \pm\delta x/\delta t\right)$ and $\left(\pm\delta x/\delta t,\ \pm\delta x/\delta t,\ \pm\delta x/\delta t\right)$ (Qian et al.

327 1992).

328 *Model for water flow*

329 The collision matrix in the model for water flow is diagonal:

$$S = \left(s_0, s_1, s_2, s_3, s_4, s_5, s_6, s_7, s_8, s_9, s_{10}, s_{11}, s_{12}, s_{13}, s_{14}, s_{15}, s_{16}, s_{17}, s_{18}\right)^T,$$

$$s_0 = s_3 = s_5 = s_7 = 0,$$

$$s_1 = s_2 = s_{9-15} = 1/\tau, \tag{A2}$$

$$s_4 = s_6 = s_8 = s_{16-18} = 8(2 - \tau^{-1})/(8 - \tau^{-1}),$$

331   and the equilibrium distribution functions are

$$f_i^{eq} = w_i \left[\rho + \rho_0 \left(\frac{3e_i \cdot u}{s^2} + \frac{9(e_i \cdot u)^2}{2s^4} - \frac{3u \cdot u}{2s^2} \right) \right],$$

332    $w_0 = 1/3,$

$w_i = 1/18, \qquad \|e_i\| = \delta x / \delta t$ \tag{A3}

$w_i = 1/36 \qquad \|e_i\| = \sqrt{2}\delta x / \delta t$

333   where $s = \delta x / \delta t$ and ρ_0 is a reference fluid density to ensure an incompressible fluid at steady

334   state (Zou et al. 1995). The water density ρ and bulk water velocity u are calculated from

$$\rho = \sum_{i=0}^{18} f_i,$$

$$u = \sum_{i=1}^{18} f_i e_i / \rho_0. \tag{A4}$$

336   The kinematic viscosity of fluid was $\nu = \delta x^2 (\tau - 0.5)/6\delta t$ and its pressure is related to density

337   in $p = \rho \delta x^2 / 3\delta t^2$.

338   *Model for solute diffusion*

339   The equilibrium distribution functions for solute diffusion are defined by

340        $f_i^{eq} = w_i c,$ \tag{A5}

341   where c is solute concentration and the weighting parameter w_i is the same as those defined in

342   Eq. (A3). The diagonal collision matrix for solute diffusion is uniform:

343    $S = \left(\tau_0, \tau_0, \tau_0, \tau_0, \tau_0, \tau_0, \tau_0, \tau_0, \tau_0, \tau_0, \tau_0, \tau_0, \tau_0, \tau_0, \tau_0, \tau_0, \tau_0, \tau_0, \tau_0\right)^T,$ \tag{A6}

344   The collision can thus be directly calculated from $m = \tau_0 \left[f_i^{eq}(x,t) - f_i(x,t) \right]$ without need of

345   the transform as for fluid flow. The concentration c and the diffusice flux j in each voxel are

346   calculated from

347
$$c = \sum_{i=0}^{18} f_i^{eq},$$
$$\boldsymbol{j} = \sum_{i=0}^{18} (1 - 0.5/\tau_0) e_i f_i^{eq},$$
(A7)

348 The mollecular diffusion coefficient in the above model is $D_0 = \delta x^2 (1/\tau_0 - 0.5)/6\delta t$. The

349 effective diffusion coefficient of the image was calculated using the method proposed in our

350 previous work (Zhang et al. 2016a).

351 *Model implementation*

352 For both water flow and solute diffusion, there are two calculations to advance one time step.

353 The first one is to calculate the collisions: $f_i^* = f_i(\boldsymbol{x},t) + M^{-1}SM\left[f_i^{eq}(\boldsymbol{x},t) - f_i(\boldsymbol{x},t)\right]$ for water

354 and $f_i^* = f_i(\boldsymbol{x},t) + \tau_0\left[f_i^{eq}(\boldsymbol{x},t) - f_i(\boldsymbol{x},t)\right]$ for solute, and the second step is to move f_i^* to

355 $\boldsymbol{x} + \delta t \boldsymbol{e}_i$ at the end of δt. Whenever f_i^* hits a solid voxel during the streaming, it is bounced

356 back to where it emanates to ensure a zero velocity on the water-solid interface for both water

357 flow and solute diffusion.
