Research highlight

- LUR application in the mountainous high-density urban scenario.
- Wind environment were quantified by using the surface geomorphometrical analysis.
- Wind availability information was incorporated into LUR modelling.
- Wind variables show in most resultant models as significant independent variables.
- A maximum increase of 20% is achieved in the annual averaged NO₂ model performance.

Graphical abstracts

Abstract

Urban air quality serves as an important function of the quality of urban life. Land use regression (LUR) modelling of air quality is essential for conducting health impacts assessment but more challenging in mountainous high-density urban scenario due to the complexities of the urban environment. In this study, a total of 21 LUR models are developed for seven kinds of air pollutants (gaseous air pollutants CO, NO₂, NO_x, O₃, SO₂ and particulate air pollutants PM_{2.5}, PM₁₀) with reference to three different time periods (summertime, wintertime and annual average of 5-year long-term hourly monitoring data from local air quality monitoring network) in Hong Kong. Under the mountainous high-density urban scenario, we improved the traditional LUR modelling method by incorporating wind availability information into LUR modelling based on surface geomorphometrical analysis. As a result, 269 independent variables were examined to develop the LUR models by using the “ADDRESS” independent variable selection method and stepwise multiple linear regression (MLR). Cross validation has been performed for each resultant model. The results show that wind-related variables are included in most of the resultant models as statistically significant independent variables. Compared with the traditional method, a maximum

1 increase of 20% was achieved in the prediction performance of annual averaged NO₂
2 concentration level by incorporating wind-related variables into LUR model
3
4 development.

1. INTRODUCTION

Urban air quality serves an important function in urban living quality. People living in cities, especially those in megacities, are facing severe health threats resulted from urban air pollution issues (Gurjar et al., 2010; Zhu et al., 2012). As a robust and efficient technique to estimate air pollution concentration level, land use regression (LUR) has been widely adopted to map the spatial distribution of outdoor air pollution (Hoek et al., 2008) and assess the long-term human health exposure (Ryan and LeMasters, 2007). Since its first application in the investigation of intra-urban traffic-related air pollution in European cities (Briggs et al., 1997), LUR models have been developed for many cities and regions, such as Europe (Beelen et al., 2013; Vienneau et al., 2009), North America (Hystad et al., 2011; Novotny et al., 2011), Asia (Kashima et al., 2009) and Australia (Knibbs et al., 2014). Using real monitored data, LUR estimates the ambient air pollution concentration at unmonitored locations based on the surrounding land use, population and traffic conditions with empirical regression modelling techniques. Compared with other methods of air pollution concentration modelling, the main advantage of LUR is that the mapping of small-scale variability is able to provide a more accurate evaluation of the health risks in unmonitored sites when dealing with the difficulty of epidemiological studies on the health impacts of human exposure to outdoor air pollution (Briggs et al., 1997).

The model performance of most LUR cases are reasonably good in many air

1 pollution exposure studies (Ryan and LeMasters, 2007). However, its performance in
2 high-density mountainous areas remains unknown, because so far most LUR case
3
4
5 cites/regions have either flat terrain or relatively low-density urban development or
6
7 both. In areas with mountainous topography, the complex surface morphology
8
9 strongly perturbs the boundary layer wind field (Finardi et al., 1998; Raupach and
10
11 Finnigan, 1997). The high-density building environment significantly alters the
12
13 aerodynamic roughness of land surface (Grimmond, 1998; Kastner-Klein and Rotach,
14
15 2004), and consequently, changes the sub-layer wind flows and the dynamic potential
16
17 of atmospheric pollutant dispersion (Bottema, 1997). It has been demonstrated that
18
19 wind plays an essential role on the movement, concentration and dispersion of air
20
21 pollution (Cogliani, 2001; Pasquill, 1971; Seaman, 2000). In mountainous and high-
22
23 density Hong Kong, the interaction between the hilly topography, high-density
24
25 building morphology and wind fields are very complex, which makes the wind
26
27 availability vary vastly between different locations (Tong et al., 2005) and leads to
28
29 significant spatial variations of air pollution concentrations (Wang et al., 2001).
30
31 Therefore, it is essential to take wind conditions into account, while modelling air
32
33 pollution using LUR.
34
35
36
37
38
39
40
41

42
43 However, few efforts have been made to take wind information and
44
45 meteorological variables into consideration in the LUR modelling of air pollution
46
47 concentrations (Arain et al., 2007; Su et al., 2008). Wind fields simulated by a
48
49 regional weather forecasting model were used in a study which used LUR model to
50
51 predict NO₂ concentrations for the links between health and exposure before (Arain et
52
53 al., 2007). The study results show that the use of wind variables can significantly
54
55 improve the LUR model performance but also indicate that the complex wind field on
56
57 a local scale cannot be fully reproduced by only using the regional weather
58
59

1 forecasting model. An attempt to simulate the wind field within the urban boundary
2 layer over the complex terrain using the National Center for Atmospheric Research
3 Mesoscale Model, version 5 (MM5), of Hong Kong has been made with a resolution
4 of 500m (Tong et al., 2005). However, the modelling output of the above study only
5 lasts a short period of three days, therefore, still didn't provide sufficient wind
6 information for the LUR modelling in this present study.
7
8
9
10
11
12
13

14
15 Another method of incorporating wind information into air pollution LUR
16 modelling is to integrate a source area (SA) air dispersion box model into LUR
17 models. Box model is the simplest air dispersion model type which approximates the
18 study domain as a defined 3D space with definite sides, top and bottom, in which
19 pollutants are emitted and relevant physical processes/chemical reactions can be
20 monitored (R.J. Allen, 1975). In previous studies (Ainslie et al., 2008; Su et al., 2008),
21 a homogeneous meteorological condition was set for each 3D wedge-shaped source
22 area in the LUR study area, so the wind information can be integrated into the LUR
23 modelling. However, it remains unknown if such simplification of meteorological
24 conditions and uniformity throughout in the box can well represent the influence of
25 complex and heterogeneous local terrains on wind conditions. Therefore, for the LUR
26 development in Hong Kong, other methods should be tested to deal with the
27 mountainous and high-density city scenario.

47 In this paper, we estimate and incorporate the fine scale spatial information of
48 wind availability into LUR modelling to predict air pollution concentration in a
49 mountainous high-density city scenario by using Hong Kong as a case. We
50 innovatively adopt the interdisciplinary knowledge of surface geomorphometry to
51 estimate local wind availability to improve the LUR model prediction accuracy of air
52 pollution concentration.

2. MATERIALS AND METHODS

In this present study, local wind conditions were investigated using the meteorological records during an extended period observed by the network of 36 automatic weather stations (AWSs) operated by the Hong Kong Observatory (HKO). With the information of local wind conditions, the fine-scale spatial distribution of wind availability represented by several geomorphometrical parameters was calculated and mapped in the geographical information system (GIS) as high-resolution raster data layers. Data derived from these data layers of wind availability are integrated into the LUR modelling process as independent variables to improve the model's performance. Figure 1 briefly illustrates the workflow of this present study.

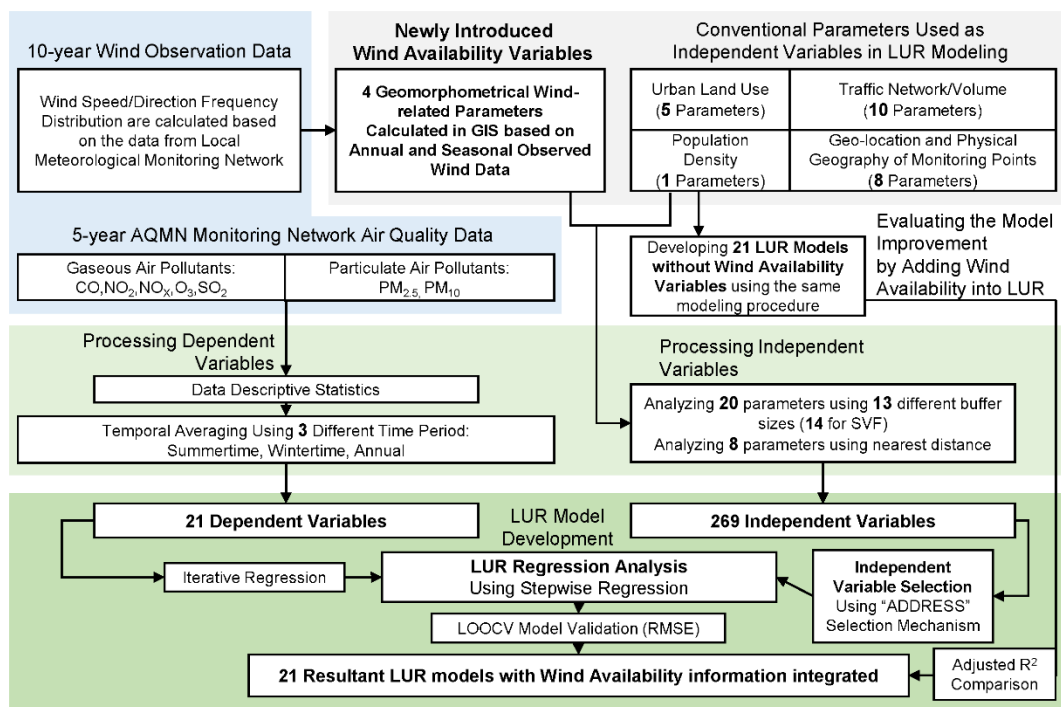

Figure 1. The workflow chart of this present study.

2.1. Study Area and Context

Hong Kong - a mountainous high-density megacity - is selected as the study area in this paper. Hong Kong is situated at 22° 15' N, 114° 10' E and has an area of approximately 1100 km². It has a population of over seven million, which makes it

1 one of the largest megacities in Asia and also around the world. The climate of Hong
2 Kong is subtropical maritime type according to the Koppen Climate Classification,
3
4 which features hot and humid summers, and warm winters of seasonal mean
5
6 temperature of 23.3°C and 18.2°C respectively (HKO, 2015). The annual mean
7
8 rainfall measures 2398.5mm. The annual prevailing wind of Hong Kong is basically
9
10 easterly with the annual mean wind speed in high-density urban area measuring
11
12 11.0km/h and in open rural area 23.3km/h. It should be emphasized that Hong Kong
13
14 experiences very complex wind environments as a result of the combination of its
15
16 mountainous topography, high-density urban morphological characteristics, land and
17
18 sea breeze circulation, and the alternation of the subtropical monsoon (Chin, 1986;
19
20 Yan, 2007).

27 **2.2. Data Collections**

28 **2.2.1. Observed Wind Information**

29
30 The 5-year (2011-2015) long-term meteorological records of hourly wind speed (v ,
31
32 m/s) and direction ($Wdir$, 0-360°) observed by a network of 36 AWSs (Figure 2) were
33
34 collected from the HKO. The metadata of these collected wind data were also
35
36 collected to describe the location, surroundings and the height of the anemometer of
37
38 each AWS. Annual and seasonal probability distributions of v and $Wdir$ of the
39
40 location of each AWS were calculated using observed wind data to provide the basic
41
42 information of estimating the spatial variation of wind availability in Hong Kong
43
44 (Figure 3).

2.2.2. Long-term Monitoring Data of Air Pollution Concentrations

1
2 Long-term hourly air pollution data of high temporal resolution recorded in the recent
3
4 five years (from 2011 to 2015) by the local air quality monitoring network (AQMN)
5
6 of the Hong Kong Environmental Protection Department (HKEPD) were collected to
7
8 develop the LUR models for different air pollutants. Data of the hourly averaged
9
10 concentrations of gaseous air pollutants CO (carbon monoxide), NO₂ (nitrogen
11
12 dioxide), NO_x (nitrogen oxides), O₃ (ozone), SO₂ (sulfur dioxide) and particulate air
13
14 pollutants PM_{2.5} [particulate matters with aerodynamic diameter less than or equal to
15
16 2.5 μm, also known as fine particulate matter (FSP)], PM₁₀ [particulate matters with
17
18 aerodynamic diameter less than or equal to 10 μm, also known as respirable
19
20 particulate matter (RSP)] were collected from the 15 air quality monitoring stations
21
22 (AQMSs) of AQMN (Figure 2). The annual and seasonal averages (summer time -
23
24 May to Aug, wintertime - Dec to Feb) of different air pollutants are calculated with
25
26 AQMN data. They are then used as dependent variables to develop the LUR models
27
28 (Figure 4).

2.3. Estimating the Spatial Distribution of Wind Availability in Hong Kong

Air pollution concentration is significantly determined by the local wind availability, which is highly related to the surface topography. Urban climate research shows that wind condition is closely related to the physical interactions between the land surface and the atmosphere (Arnfield, 2003). Wind field is largely determined by the heterogeneous spatial distribution of the air pressure as a result of the irregular surface topography and various surface roughness properties (Landsberg, 1981). For example, a mountain usually traps air pollutants on its leeward side. Wind conditions are also significantly affected by the urban surface roughness in urban built-up areas (Bottema, 1997). Therefore, it is essential to determine the surface topographical characteristics and spatial distribution of the surface roughness to estimate the wind availability of different localities. Hence, it is necessary to consider the land surface topographical/morphological parameters as independent variables in LUR modelling

in the case of Hong Kong to improve the prediction accuracy.

By using geomorphometrical methods, land surface parameters were calculated and used to estimate the openness of the local topography to the background wind. Geomorphometrical methods are able to indirectly depict the long-term local wind availability at a reasonable accuracy and fine spatial resolution without involving intensive computational resources and massive time consumption (Böhner and AntoniĆ, 2009). Four land surface topographical/morphological parameters that have been widely used in topo-climatological studies – windward/leeward index, sky view factor (SVF), frontal area index (FAI, λ_F) and roughness length (z_0)— are selected and calculated at a series of LUR buffers as the independent variables to represent the wind availability in LUR modelling. The windward/leeward index reflects the influence of the natural topography on the wind availability at a relatively large-scale. SVF and FAI are good indicators of the intra-urban wind condition with respect to the local-scale building morphology. z_0 is the roughness length that comprehensively depict the surface aerodynamic properties.

The windward/leeward index is a land surface topographical parameter that describes the spatial relationship between the land surface slope aspect and a specific wind direction (Böhner and AntoniĆ, 2009). The angle between the slope aspect α of a certain location and wind direction θ is $\alpha_{r(\theta)}$ which ranges from 0° (fully windward) to 180° (fully leeward). The wind direction-weighted windward/leeward index (ranges from 1 - windward positions to -1 - leeward positions) of a certain location can be calculated with its corresponding wind direction probability $P_{(\theta)}$ from 16 main directions θ :

$$\text{Windward/leeward index} = \sum_{\theta=1}^{16} \cos \alpha_{r(\theta)} \cdot P_{(\theta)}$$

1 SVF is a topographical/morphological parameter that describes the openness
2 of a specific location at land surface to the open sky hemisphere (Watson and
3 Johnson, 1987). SVF ranges from 0 (which represents a theoretical circumstance that
4 the location is completely blocked by the surrounding topography) to 1 (which
5 indicates a complete openness to the sky hemisphere). SVF is usually used to explain
6 the solar radiation and air temperature variations. Moreover, it is also one of the most
7 important indicators related to wind availability and pollution dispersion and other
8 environmental factors (Eliasson et al., 2006; Rafieian et al., 2014; Ratti and Richens,
9 1999). It has been found by two previous LUR studies that the prediction accuracy of
10 urban air quality improves when SVF is included in LUR modelling (Eeftens et al.,
11 2013; Tang et al., 2013). With a 2m-resolution digital surface model (DSM) of Hong
12 Kong generated from Hong Kong Planning Department (PlanD) data sources, the
13 SVF were calculated (Figure 5) by using the equation proposed by Dozier and Frew
14 (1990):

$$SVF = \frac{1}{2\pi} \int_0^{2\pi} [\cos \beta \cos^2 \varphi + \sin \beta \cdot \cos(\Phi - \alpha) \cdot (90 - \varphi - \sin \varphi \cos \varphi)] d\Phi$$

15 where SVF is calculated for each point location of the DSM with slope aspect α and
16 angle β based on the horizon angles φ in azimuth directions Φ of the hemisphere
17 circle with the radius d .

Figure 5. Input DSM of Hong Kong (Tsim Sha Tsui downtown area) and output calculated SVF map.

Surface roughness is an essential factor that has been widely used in boundary layer climate research to describe the wind behaviour over the land surface (Grimmond and Oke, 1999). The roughness properties of land surface affect the surface drag, turbulence intensity, wind velocity and vertical wind profile (Landsberg, 1981). It means the wind availability of a locality is highly dependent on the local natural topography and urban morphology, because roughness varies in different areas due to the differences in topographical and morphological characteristics (Grimmond and Oke, 1999; Raupach and Finnigan, 1997). It has been confirmed that surface roughness is essential for the air quality modelling (Barnes et al., 2014; Bottema, 1997). The complex terrain and high density of Hong Kong mean the city's surface roughness properties vary vastly, and so does the wind environment. The spatial distribution of air pollution will be affected accordingly.

Surface roughness can be estimated using the Davenport roughness classification (Wieringa, 2001), through field observation using the anemometric methods (Grimmond, 1998), or from surface morphometric analysis using geomorphometrical methods (Grimmond and Oke, 1999). Although the Davenport

1 classification has been widely adopted to estimate surface roughness for low-density
2 and mid-density city scenarios, previous research indicates that this method is not
3
4 suitable for estimating the spatial distribution of surface roughness in high-density
5
6 city scenario (Ng et al., 2011) because high-density urban areas usually belong to the
7
8 “chaotic” surface classification with the surface roughness length value $z_0 > 2$. That
9
10 means no more detailed classification can be made to estimate the intra-urban
11
12 variation within high-density urban areas. Anemometric methods have been adopted
13
14 to measure the atmospheric turbulence both in urban areas (Brook, 1972) and in
15
16 suburban areas (Duchene-Marullaz, 1975). However, it is not a practical way to
17
18 estimate surface roughness due to the need for high quality field measurement and the
19
20 lack of clear optimal methods (Grimmond, 1998). Therefore, the geomorphometrical
21
22 method has become the most popular tool in recent years, and is used in this study to
23
24 describe the spatial distribution of surface roughness as independent variables to be
25
26 incorporated into LUR models.
27
28
29
30
31
32

33
34 The geomorphometrical methods estimate the surface roughness
35
36 characteristics by using empirical modelling based on the morphometric
37
38 characteristics of land surface (Bottema, 1996; Macdonald et al., 1998; Raupach,
39
40 1992). The basic calculation method of z_0 was mentioned by Bottema (1996) for
41
42 regular building clusters:
43
44

$$45 \quad z_0 = [h - h \cdot (\lambda_P)^{0.6}] \exp\left(-\frac{K}{\sqrt{0.5 \cdot C_{Dh} \cdot \lambda_F}}\right)$$

46
47 where h is building height, λ_P and λ_F are the building coverage ratio and building FAI
48
49 of a building lot. C_{Dh} is drag coefficient (constant of 0.8) and K is the Kármán's
50
51 constant (considered as 0.4). The calculation of λ_P and λ_F are shown in following
52
53 equations:

$$\lambda_P = (\sum_{i=1}^n A_{Pi})/A_T$$

$$\lambda_F = (\sum_{i=1}^n A_{Fi})/A_T$$

where n is the total number of building in the urban lot (Figure 6). Therefore, the complete z_0 equation is as follow:

$$z_0 = \left\{ h - h \cdot \left[(\sum_{i=1}^n A_{Pi})/A_T \right]^{0.6} \right\} \exp \left[- \frac{K}{\sqrt{0.5 \cdot C_{Dh} \cdot (\sum_{i=1}^n A_{Fi})/A_T}} \right]$$

In Hong Kong, particularly in some high-density downtown areas, the building geometry and layout are extremely irregular due to the mountainous topography.

Therefore, the improved calculation method developed by Gál and Unger (2009) is adopted to deal with the irregular building geometries and layouts. This method uses the Voronoi diagram for the partitioning of building lot polygons so that the relevant roughness parameters can be calculated for each lots (Figure 7). The λ_F of each building lot depends on the wind flow direction. In this present study, λ_F was calculated using 16 wind equiangular directions (Figure 6). Then, the weighted average of λ_F was calculated according to the annual and seasonal wind direction probability distribution mentioned in section 2.2.1, so the seasonal variation of wind availability could be incorporated into the LUR modelling:

$$\bar{\lambda}_F = \sum_{\theta=1}^{16} \lambda_{F(\theta)} \cdot P_{(\theta)}$$

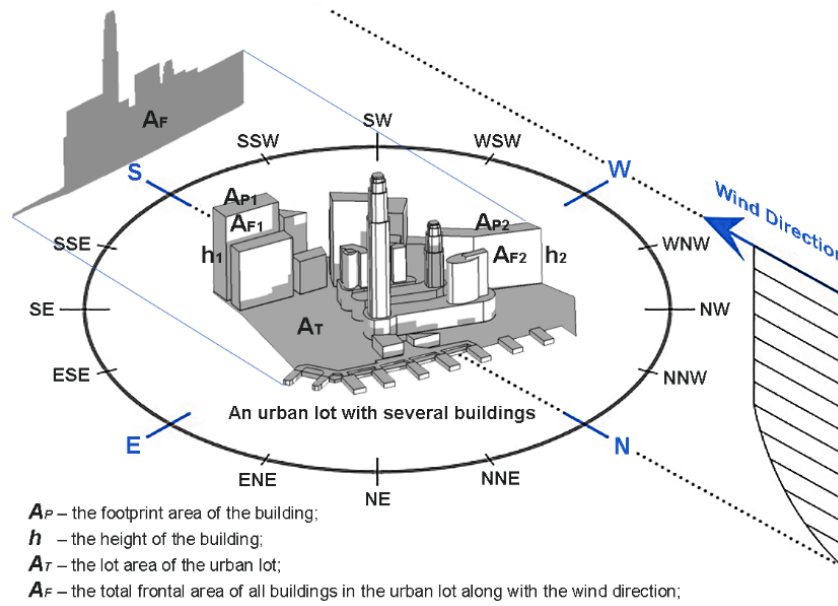

Figure 6. Demonstration of FAI Calculation using 16 wind directions.

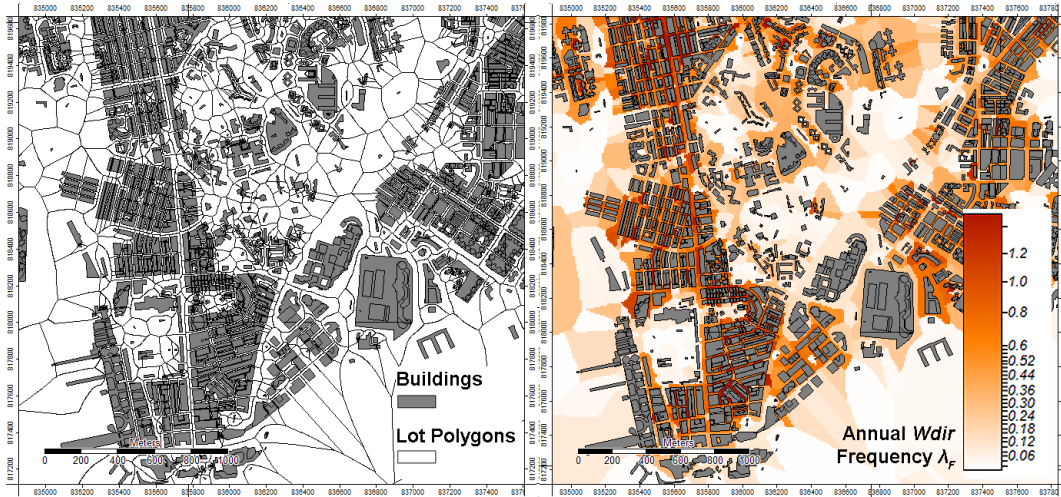

Figure 7. Generated lot polygons for building and calculated annual Wdir probability distribution weighted average λ_F value.

2.4. Independent/Dependent Variables of LUR Modelling

As suggested in many previous LUR studies (Hoek et al., 2008), independent variables were prepared for LUR modelling according to the following four classifications: (1) traffic network/volume, (2) urban land use, (3) population density, (4) geo-location and physical geography of monitoring points. As mentioned, four other parameters related to the wind availability were also prepared as independent

variables to depict the influence of the wind environment on LUR model performance. This present study calculated 20 parameters using 13 different buffers (14 for SVF) and 8 parameters using nearest distance analysis for each sampling point to check all potential independent variables for the LUR models for air pollution of Hong Kong (Table 1). In total, 269 potential independent variables were prepared and analysed in this study.

Table 1. List of all independent variables used in this study for LUR modelling.

| PARAMETERS USED AS INDEPENDENT VARIABLES | | UNITS | ANALYSIS METHODS | ABBREVIATION |
|---|---------------------------------|----------------------------|---------------------|--------------|
| Traffic Network/Volume | | | | |
| Road network line density | Expressways and trunk road | km/km ² | Buffer ^a | EXP |
| | Primary road | km/km ² | Buffer | PRI |
| | Secondary road | km/km ² | Buffer | SEC |
| | Tertiary road | km/km ² | Buffer | TER |
| | Ordinary road | km/km ² | Buffer | ORD |
| Road area ratio (%) | | % ^b | Buffer | RDA |
| Traffic volume | Public transport vehicles | Passenger Car Units (PCUs) | Buffer | PTPCU |
| | Private and government vehicles | PCUs | Buffer | PGPCU |
| Count of bus stops | | number | Buffer | BUSST |
| Distance to marines ports & routes | | km | Distance | MARINE |
| Urban Land Use | | | | |
| Land use area | Residential | m ² | Buffer | RES |
| | Commercial | m ² | Buffer | COM |
| | Industrial | m ² | Buffer | IND |
| | Government | m ² | Buffer | GOV |
| | Open space | m ² | Buffer | OPN |
| Population Density | | | | |
| Population density | | person/km ² | Buffer | POP |
| Geo-location and Physical Geography of Monitoring Points | | | | |
| Longitude (Δx to the coordinate origin of HK1980 Gird) | | m | Distance | LNG. |
| Latitude (Δy to the coordinate origin of HK1980 Gird) | | m | Distance | LAT. |
| Elevation above the Hong Kong Principal Datum ("mPD") | | m | Distance | ELEV. |
| Distance to waterfront | | km | Distance | WATER |
| Distance to local power plants | | m | Distance | POWER |
| Distance to city parks | | km | Distance | CITYPARK |
| Distance to country parks | | km | Distance | COUNTRYPARK |
| Greening coverage ratio | | % | Buffer | GCR |
| Wind Availability^c | | | | |
| Sky view factor (SVF) ^d | | [0-1] | Point, Buffer | SVF |
| Wind effect (Windward/leeward index) | Annual | Dimensionless quantity | Buffer | WE_ANN |
| | Summertime | | | WE_SUM |
| | Wintertime | | | WE_WIN |

| | | | | |
|---|------------|------------------------|--------|------------|

Hence, besides mean SVF in different buffers, point SVF values are also retained as an independent variable (defined as 0 m buffer, directly use the abbreviation – SVF without showing buffer size).</p> | | | | |

Annual, summertime and wintertime average long-term concentration of seven air pollutants (CO, NO₂, NO_x, O₃, SO₂, PM_{2.5} and PM₁₀) were calculated and used as the dependent variables for LUR modelling. As such there were 21 resultant LUR models produced by this present study. The reason for separately modelling the air pollution concentration for different seasons is that the seasonal variation of the meteorological conditions of Hong Kong is considerable. In Hong Kong, because of the seasonal variation of monsoons, the prevailing synoptic wind directions are northerly and northeasterly in wintertime, mainly easterly during spring and autumn seasons, and southerly wind dominates the summer months (Guo et al., 2007; Sin et al., 2002; Yan, 2007). Consequently, the overall air pollution concentration level is significantly affected by the long-distance transportation of pollution from sources in the Pearl River Delta (PRD) region in mainland China during the wintertime (Kwok et al., 2010; Yuan et al., 2006), while in summertime, it is dominated by local emission sources (Lau et al., 2007). Separately conducting LUR modelling for different seasonal periods provides a clear estimation of the contribution of local sources, identifies the local determinants of the spatial distribution of air pollution in Hong Kong and also helps to evaluate the regional impacts from surrounding areas of Hong Kong.

2.5. LUR Modelling Process

2.5.1. Independent Variables Selection

In this study, instead of manually conducting the exploratory regression modelling, we adopted the widely used stepwise regression technique which is an iterative regression modelling method that automatically selects independent variables by testing statistical significance of regression models (Tabachnick and Fidell, 2001). It has been found that introducing too many independent variables into a stepwise multiple regression modelling process will cause spurious regressions and usually leads to over-fitted multiple regression models (Tu et al., 2005). To avoid this issue, “A Distance Decay REgression Selection Strategy (ADDRESS)” developed by Su et al. (2009) was adopted to preliminary filter all independent variables. Firstly, a series of distance-decay curves were plotted for different buffers using the correlation coefficient (R) between the dependent variables of concentration of seven air pollutants and each LUR parameter. Then, by strictly following the independent variable selection mechanism developed by Su et al. (2009), independent variables at the optimal buffer sizes for the air pollution concentration are selected as the candidate independent variables before further regression modelling.

It is known that collinearity among independent variables causes over-fitting issues and spurious resultant regressions as well (Tu et al., 2005). Therefore, multivariate statistical analysis is used to examine the correlations between the independent variables preliminary selected by using “ADDRESS”. Together with variance inflation factor (VIF), the results of the multivariate analysis provide a reference to detect hidden correlations between independent variables in the resultant models to maintain statistical reliability.

2.5.2. Stepwise Regression LUR Modelling and Model Validation

Stepwise regression has been used for selecting independent variables for a long time and was developed in the form of an automatic computer program to deal with the complexity of multiple regression statistical studies (Jennrich, 1977; Miller, 2002; Miller, 1984) (Section 1.1, supplemental material). In this study, SAS JMP statistical software package was used in order to find the optimal LUR models as determined by the minimum Akaike information criterion (AICc) (Freund et al., 2003; Sall et al., 2012). The adjusted R^2 values and leave-one-out cross validation (LOOCV) root-mean-square error (RMSE) of generated models were examined to check the model performance (Section 1.2, supplemental material). A strict set of criteria based on the VIF (independent variables with $VIF < 2$) was adopted to screen out independent variables with significant collinearity to produce the final models.

3. RESULTS AND DISCUSSIONS

3.1. Patterns in Distance-Decay Curves of Independent Variables

The “ADDRESS” selection mechanism has been described in detail in other research articles (Su et al., 2009). In our study, a total of 21 groups of distance-decay curves (420 curves in total) were plotted to portray the average concentrations over the past five years of seven kinds of air pollutants in three time periods. Each distance-decay curve group has 20 curves correspondingly depicting the correlation between the pollution concentrations and the 20 buffer-based parameters listed in Table 1. An example of distance-decay curve groups is shown in Figure 8, which shows the dependent variables of annual average NO_2 concentration. High correlations ($R > 0.8$) can be clearly identified between the wind-related variables (SVF, FAI and z_0) and NO_2 level. Similar results are founded in curves for other pollutants as well, reflecting the significance of local wind condition on the estimation of air pollution

concentration.

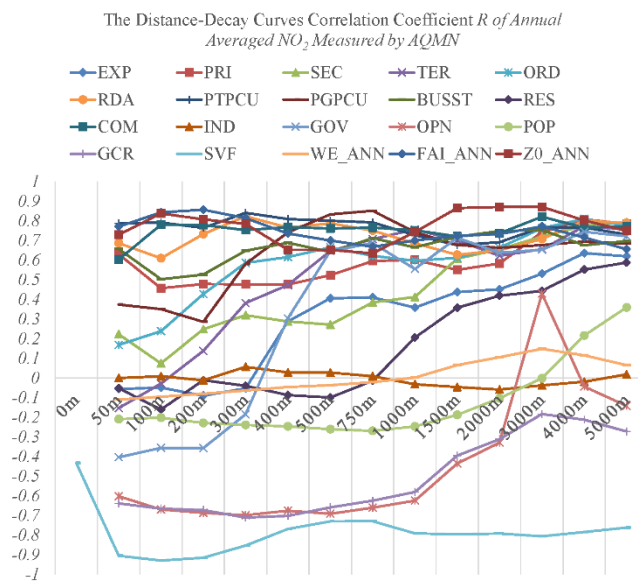

Figure 8. The Distance-Decay Curves of R between all independent variables (at a series of buffers) and the annual averaged NO₂ concentration level (please also see Figure S-1 in the supplemental material for more illustration).

Besides the high correlation between wind-related variables and pollution concentrations, several other common characteristics are observed from these distance-decay curves: Firstly, as functions of the buffer distance, the distance-decay curves for summertime usually have simpler and clearer trends than the wintertime's ones. Most of summertime curve contains only one or two peaks, and didn't change between positive and negative. In contrast, wintertime curves are more complex and irregular. Considering that the LUR modelling in this study focuses on using local urban database as independent variables, this observation clearly reflects the seasonal variation of the dominant air pollution modes caused by the seasonal variation of the monsoon between summer (local emission dominant) and winter (combination of both local emission and strong regional impacts from PRD) (Kwok et al., 2010; Yuan et al., 2006). Secondly, the trends of annual distance-decay curves for most pollutants are more similar to the summertime distance-decay curves than the wintertime curves.

1 This indicates the dominance of local emissions in long-term air pollution
2 concentration levels although regional emissions do have considerable contribution to
3
4 severe air-pollution episodes which usually occur during wintertime (Fung et al.,
5
6 2005). Thirdly, many curves have a two-peak trend with one peak at a smaller buffer
7
8 (between 50m and 400m) and the other at a much larger buffer (between 2000m and
9
10 5000m). This finding implies that the same LUR parameter considerably affects the
11
12 concentration level at two buffers via different mechanisms on different climatic
13
14 scales. The smaller optimal buffer suggests the effect of a local phenomenon on
15
16 small-scale air pollution variation, while the larger optimal buffer possibly reveal a
17
18 regional impact on large-scale air pollution distribution. The same pattern also came
19
20 up in Su et al. (2009)s' LUR study. The high $|R|$ at the larger optimal buffer confirms
21
22 that the AQMN is appropriate for general air quality monitoring in Hong Kong. The
23
24 locations of AQMSs are reasonable for the purpose of monitoring the long-term air
25
26 quality of its corresponding areas. However, the peak in the smaller buffer distance on
27
28 many LUR parameters decay curves also reflects the local influence on the long-term
29
30 air quality monitoring results. This also implies that the spatial coverage of AQMN
31
32 should be further developed in order to catch more detailed information on local
33
34 variation of air pollution concentrations.

45 **3.2. Resultant LUR Models**

46 Finally, a total of 21 LUR models are developed for seven kinds of air pollutants
47
48 (gaseous air pollutants CO, NO₂, NO_x, O₃, SO₂ and particulate air pollutants PM_{2.5},
49
50 PM₁₀) with reference to three different time periods (summertime, wintertime and
51
52 annual average of hourly monitoring data). Table 2 shows the 21 resultant LUR
53
54 models. It is found that wind availability-related independent variables such as SVF,
55
56 FAI are involved in many of these resultant models, which indicates that wind
57
58
59
60
61
62
63
64
65

availability information plays an important role in modelling air pollution in a mountainous high-density city.

Table 2. The structure and performance of resultant LUR models include wind availability as independent variables (all independent variables with VIF < 2).

| Air Pollutant | Time Period | Resultant LUR Model | Adjusted R ² | LOOCV RMSE | p-value |
|-------------------|-------------|--|-------------------------|------------|---------|
| CO | Annual | 45.810+(2.132e-7)(COM5000)+47.628(FAI ANN0200) | 0.844 | 9.286 | 0.0016 |

3.2.1. Identifying the Dominant Impact Factors of Air Quality in Hong Kong

Four types of commonly shared independent variables by resultant models are clearly identified - traffic-related, geographical location of monitoring locations, urban land

1 use and wind availability. In Hong Kong, road transport is the main contributor to CO
2 emissions and is also accountable for a large proportion of NO_x and PM emissions
3
4 (Zues Wan et al., 2015). Traffic-related variables include the line density of several
5
6 road types, road area ratio, vehicle traffic volumes and number of bus stops. These
7
8 largely represent the emission intensity of the aforementioned air pollutants. The
9
10 presence of these traffic-related variables in the resultant models confirms transport is
11
12 one of the determinants of several air pollutants in Hong Kong. Locations of
13
14 monitoring points prove to provide good estimations of local air pollution as well. The
15
16 variables of distance from the monitoring locations to marine ports/routes and local
17
18 power plants are included in the models of SO₂, which is consistent with the emission
19
20 inventory that has identified marine transport and public electricity generation as two
21
22 of the determinants of SO₂ emission in Hong Kong (Lau et al., 2007). The variable of
23
24 distance to the country park in the NO_x models quantitatively depicts the urban-rural
25
26 contrast of air quality. Like other cities, land use pattern is also a key factor in the
27
28 concentration level and spatial distribution of air pollution. The spatial pattern of
29
30 commercial (COM), residential (RES) and industrial (IND) land use areas directly
31
32 represent the spatial distribution air pollutant emissions from human activities, while
33
34 the open land use (OPN) areas in Hong Kong are usually vegetation and open space.
35
36 It has been proved that vegetation plays an important role in air pollution reduction in
37
38 megacities (Yang et al., 2005). The open land use indicates a much lower urban
39
40 density which has lower emission intensity and also more effective pollution
41
42 dispersion. As to the wind availability, as expected, wind-related variables also show
43
44 in the resultant models as significant independent variables. These wind-related
45
46 independent variables include SVF, FAI and z_0 .

3.2.2. Wind-related Variables in the Resultant LUR Models of Air Pollutants

1
2
3
4 Table 2 shows that wind-related variables (SVF, FAI and z_0) are included in 14 of all
5
6 of the 21 resultant LUR models. SVF measures the openness to sky which represent
7
8 the vertical permeability of a certain locality to the atmosphere. Previous pollution
9
10 dispersion studies conclude that the retention time of air pollutants in a street canyon
11
12 with aspect ratio (H/W) of 2.0 is doubled and tripled respectively, when compared
13
14 with a street canyon with H/W of 1.0 and 0.5 (Liu et al., 2005), because deep street
15
16 canyons with high H/W geometrically introduce a low SVF. As a result of this present
17
18 study, SVF (point based SVF value) and SVF0100 (averaged SVF value calculated
19
20 using the buffer size of 100m) shows in all models of NO₂ and NO_x. The significance
21
22 of SVF in LUR modelling of NO₂, NO_x and PM₁₀ in this present study has been
23
24 proven to be highly consistent with some previous LUR studies (Eeftens et al., 2013;
25
26 Tang et al., 2013). Increasing FAI reduces the horizontal permeability to the urban
27
28 ventilation, and impedes pollution dispersion as a result. Both the FAI and z_0 have
29
30 been used in the detection of urban air path to enhance urban air ventilation (Gál and
31
32 Sümeghy, 2007; Gál and Unger, 2009). The above findings imply that the spatial
33
34 pattern of most air pollutants are complex and quite heterogeneous under a
35
36 mountainous and high-density urban context. The concentration levels of air
37
38 pollutants (especially CO, NO_x and PM, which are highly related to road transport
39
40 emission) at a certain location are very localized and are highly determined by the
41
42 wind availability within a small buffer (50-200m). For example, FAI0200 (FAI value
43
44 calculated using the buffer size of 200m as the independent variable) was found to be
45
46 influential to the concentration level of CO. This implies that ventilation is essential to
47
48 the dispersion of traffic-related air pollutants. In contrast, the windward/leeward index
49
50 that calculated using the digital elevation model of Hong Kong only shows in SO₂
51
52
53
54
55
56
57
58
59
60
61
62
63
64
65

models (at a much larger buffer size, up to 4000m). This indicates the spatial pattern of SO₂ has a larger spatial scale than CO, NO_x and PM. This reaffirms that the main sources of SO₂ in Hong Kong are the marine emissions and local electricity generations (Lau et al., 2007). A distribution map of all marine transportation facilities and local power plants is shown in the supplemental material (Figure S-2).

3.2.3. Evaluating the Improvement on Model Performance by Incorporating Wind Availability into LUR

As described, this study comprehensively incorporates wind information into LUR modelling as the independent variables. This approach has only been adopted in a very small amount of studies. The resultant models shows that the newly introduced independent variables about wind availability are highly significant statistically, and has high prediction power in the resultant LUR models based on multivariate regression analysis (Tabachnick and Fidell, 2007). To evaluate the model performance improvement by integrating wind availability information into LUR modelling as independent variables, LUR models that only using conventional LUR independent variables are also established (Table 3).

Table 3. The structure and performance of resultant LUR models that only use conventional independent variables (all independent variables with VIF < 2).

| Air Pollutant | Time Period | Resultant LUR Model | Adjusted R ² | LOOCV RMSE | p-value |
|-----------------|-------------|---|-------------------------|------------|---------|
| CO | Annual | 63.085+0.210(ORD0500)+(3.489e-7)(COM5000) | 0.774 | 11.149 | 0.0048 |

By comparing these 21 pairs of resultant models (a side-by-side model comparison table is included in the supplemental material, Table S-1), it is found that 14 of all of the 21 models have achieved an averaged increase of 8% in prediction performance when wind availability-related parameters are added as independent variables into the LUR modelling process. The maximum increase of almost 20% is found in the LUR model of annual average concentration level of NO₂. Such improvement in NO₂ prediction is useful in controlling local traffic pollution emissions and related health risk assessments, because NO₂ is mainly emitted from Hong Kong local road transport. In the annual NO₂ model, the involved wind availability variable – SVF – measures the vertical openness and ventilation capacity of building geometry, which is highly useful and intuitive for the urban planning practice. This is because SVF is high related to a common urban planning index - H/W. In other words, LUR models with wind availability variables are not only useful in air pollution and health risk assessment but also informative for urban

environmental planning and decision making.

It should be emphasized that independent variables concerning commercial land use become important when all wind availability variables are excluded from the LUR modelling process. This indicates that commercial land use may be an alternative indicator in the modelling air quality of Hong Kong. The commercial land prices are extremely high in Hong Kong so developers tend to fill up the limited site area with tall buildings to recover the operating costs. Consequently, correlations between commercial land use and building density are high. Commercial land use also attracts a large number of visitors and consumers which leads to more intensive traffic flows, denser road networks, and an increased number of traffic facilities within or around these sites. The multivariate analysis conducted between all independent variables indicates high correlations between commercial land use (COM5000) and road transport (PRI5000 with $R^2 = 0.82$, BUSST5000 with $R^2 = 0.86$) and also urban surface geomorphometry (FAI5000 with $R^2 = 0.58$).

3.3. Limitations and Future Works

This present study models air quality of Hong Kong by using historical monitoring data from the existing air pollution monitoring network operated by local environmental protection department as dependent variables. Although the data used in this study is a 5-year long-term dataset with hourly-based high temporal resolution, the number of monitoring locations is quite limited (only 15) compared with many previous LUR studies (usually more than 20 monitoring locations) (Hoek et al., 2008) due to the limited spatial coverage of the monitoring network. The concern is that, the complex topography and heterogeneous urban development in Hong Kong make the conditions of air quality vary significantly among different locations, while many high-density and heavily trafficked areas in Hong Kong are not monitored by AQMN.

1 Moreover, most of the general/roadside AQMSs are located in relatively flat regions.
2 This is because almost all the densely-populated built-up areas of Hong Kong are in
3 those flat regions at a relatively lower elevation. It is possible that the air quality
4 estimation in those complex mountains (usually at a higher elevation) is less accurate
5 than the estimation of those densely-populated flat areas. The lack of monitoring data
6 is still a limitation of getting a good estimation in those complex mountains of Hong
7 Kong. As already mentioned in section 3.1, there is a long-term need for more
8 AQMSs to fill existing monitoring gaps. To compensate this limitation in the short-
9 term for the improvement of LUR modelling, more temporary sampling locations
10 must be carefully selected and monitored in future works to further provide sufficient
11 spatial information and a larger dependent variable dataset.

27 **4. CONCLUSION**

28 Estimating ambient air pollution concentration is essential to urban planning, policy
29 decision-making and environmental management. On the basis of the resultant LUR
30 models with the identified decisive variables on the concentration level of air
31 pollutants, our findings have clear implications for urban planners, decision makers
32 and public health officials. More importantly, there is a need to incorporate wind-
33 related information into the LUR models that estimate the air quality condition for
34 high-density cities with hilly topography. With reference to the quantitative
35 correlation indicated by these resultant models, planners can work to improve urban
36 air quality by enhancing wind availability through strategies such as reducing the FAI
37 by controlling the building height limits and ground coverage, and decreasing the
38 H/W ratio of urban street canyons. The existing local wind environment should be
39 carefully considered before assigning land use type, making site selection and
40 development plan. To be more specific, high-density or high-emission projects should

be avoided at a location with low wind availability. For example, an industrial project should not be placed in the leeward side of a mountain, so that the pollution dispersion will not be hampered by insufficient wind.

The above air quality improvement strategies must be supplemented with strategies that identify and protect the more vulnerable communities (Chau et al., 2002; Ko et al., 2007). It is necessary to combine the LUR results with local public health assessment. Moreover, it should be emphasised that above environmental planning strategies definitely contribute more than just improve air quality. Enhancing the wind availability by implementing above the environmental planning strategies will also reduce the health risks from “heat waves”. This is particularly important to high-density cities like Hong Kong, because the high-density built environment makes it more vulnerable to the extreme weather condition. It has been proven the correlation between hot weather and health impacts are considerable (Chan et al., 2012; Yan, 2000). Improving the wind environment will also improve Hong Kong’s resistance against extreme weather condition by enhancing thermal condition (Ng et al., 2011).

The linkage between urban air quality and urban planning is strong (Eliasson, 2000; Marquez and Smith, 1999). Essentially, the surface topography and aerodynamic properties are necessary components in urban planning, decision making and urban design. Therefore, with the increasing severity of air pollution related environmental issues, urban planning and design strategies are playing an increasingly important role in reducing health risks and vulnerability, building resilience and promoting living environmental quality.

ACKNOWLEDGEMENT

This research is supported by the Postgraduate Studentship (PGS) 1155005856/PHD/ARK from The Chinese University of Hong Kong. The authors would like to thank Professor Alexis Lau of the Hong Kong University of Science and Technology, Dr. Derrick Ho and Ms Ada Lee of the Chinese University of Hong Kong for their suggestion and help on this paper.
