Abstract

The high oxide ion conductivity of the proposed sodium strontium silicate ion conductors Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ (> 10$^{-2}$ S.cm$^{-1}$ at 525 °C) and its unusual alkali metal substitution strategy have been extensively questioned in the literature. Here, we present a comprehensive understanding of the structure of this material using a combination of XRD and multinuclear $^{17}$O, $^{23}$Na and $^{29}$Si solid-state NMR spectroscopy data and a detailed investigation of the Na ion dynamics by high temperature $^{23}$Na NMR line shape analysis and relaxation rates measurements. Both $^{23}$Na and $^{29}$Si NMR spectra demonstrate the absence of Na doping in strontium silicate SrSiO$_3$ and the presence of an amorphous phase identified as Na$_2$O.2SiO$_2$ glass as the Na-containing product. Devitrification at 800 °C yields crystallisation of the Na$_2$O.2SiO$_2$ glass into the known crystalline $\alpha$-Na$_2$Si$_2$O$_5$ phase which was positively identified by its XRD pattern and the extensive and clear $^{17}$O, $^{23}$Na and $^{29}$Si NMR fingerprints. High temperature $^{23}$Na NMR reveals that the Na ions are mobile in the Na$_2$O.2SiO$_2$ amorphous component below its glass transition temperature (~ 450 °C). In contrast, $^{23}$Na NMR data obtained on the crystalline $\alpha$-Na$_2$Si$_2$O$_5$ shows limited Na dynamics below ~ 650 °C and this result explains the large discrepancy in the conductivity observed in the literature which strongly depends on the thermal history of the Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ material. These insights demonstrate that the high conductivity observed in Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ are due to Na conduction in the Na$_2$O.2SiO$_2$ glass and this motivates the quest for the discovery of low temperature fast ion conductors in non-crystalline solids.
Introduction

Strontium silicate $\text{SrSiO}_3$ and alkali metal (A site aliovalent substituents) solid solutions were recently investigated as potential intermediate temperature Solid Oxide Fuel Cell (SOFC) electrolytes. Initial reports by Singh and Goodenough proposed these materials as a new family of crystal structures able to permit rapid oxygen ion vacancy conductivity, values in excess of those previously reported in the classic fluorite and perovskite type oxides.$^{1,2}$ These newly proposed superior oxide ion conductors have been reported to possess oxide ion conductivities as high as $1.04 \times 10^{-2}$ S.cm$^{-1}$ at 625 °C in the $\text{Sr}_{0.8}\text{K}_{0.2}\text{Si}_{0.5}\text{Ge}_{0.5}\text{O}_{2.9}$ material which initiated a surge of interest in these new phases.$^1$ More impressively, higher conductivity was reported in the Na analogues with the highest total conductivity of $1.79 \times 10^{-2}$ S.cm$^{-1}$ at 550 °C reported in the $\text{Sr}_{0.55}\text{Na}_{0.45}\text{SiO}_{2.775}$ composition.$^2$ The extraordinarily high values of oxide ion conductivity reported for these phases placed them at a level competitive with the state-of-the-art oxide ion conducting ceramics currently used with significant room left for further development through chemical and microstructural optimisation.

The oxygen vacancies proposed in these structures, which were assumed as the mobile defect responsible for the high level of conductivity observed, represented a new concept for designing oxide ion conducting electrolytes. Firstly, alkali metals are typically avoided in high temperature oxide ion conductors due to their ability to be highly mobile at low temperatures in solid state materials such as the well-known Garnets.$^3$ However, it has been demonstrated that Na containing oxide ion electrolytes can exist and in which the oxide ion is responsible for the high levels of conductivity.$^4$ Secondly, oxygen vacancies on SiO$_4$ tetrahedra are seldom observed in the solid state, though in this instance it was postulated that the vacancies would stimulate the formation of bridging oxide ion located between two normal oxygen sites which could be part of the mechanism for rapid oxide ion conductivity. This mechanism was supported by a $^{29}\text{Si}$ solid state Nuclear Magnetic Resonance (NMR) study by Kuang and Wu et al.$^5$
confirming the existence of a Si signal indicating breaking of the Si$_3$O$_9$ rings into Si$_3$O$_8$ chains, proposing the formation of linked tetrahedral Si in the rings. However, a high resolution powder neutron diffraction investigation suggested that whilst they observed single phase materials with the chemical composition as nominally written, they did not observe interstitial oxygen ion formation in the Fourier nuclear density difference maps from Rietveld refinements but rather oxygen vacancies in the planar oxygen sites of the corner sharing tetrahedral units of Si$_3$O$_9$.

Finally, the continuous increase reported in total conductivity as a function of alkali ion concentration absent of any obvious dopant defect interactions was very surprising as all previous oxide ion conducting systems had an optimal defect concentration for maximising total conductivity. Acceptor doped oxides typically produce a conductivity maxima at significantly lower substitutional levels than those reported in these materials,\textsuperscript{7,8} which is associated with the formation of dimer and trimer associates,\textsuperscript{9} but higher order clusters are possible, leading to the formation of nano-domains of secondary phases, detrimental to total conductivity.

An \textit{in operando} demonstration of these new oxide ion conducting electrolyte materials was reported that appeared to validate these materials as superior oxide ion conducting electrolytes, with excellent fuel cell performance results.\textsuperscript{10} The report also concluded the Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ materials were stable over the oxygen partial pressure range of $10^{-30}$ – 1 atm, preventing the deleterious effects of electronic defect contributions to the electrolyte.

In an effort to confirm the remarkable results published originally,\textsuperscript{1,2} Bayliss \textit{et al}\textsuperscript{11} attempted to replicate the study and furthermore add direct confirmation of the defect responsible for conductivity, through measurements of the oxide ion mass transport. Through detailed analysis of the structural, electrochemical and mass transport properties obtained, it was proposed that both Sr$_{0.8}$K$_{0.2}$Si$_{0.5}$Ge$_{0.5}$O$_{2.9}$, and by implication of the results the Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ materials were in fact not single phase materials but rather biphasic mixes consisting of crystalline SrSiO$_3$ and some form of amorphous glass, postulated to be potassium digerminate.
K$_2$O·2GeO$_2$ or sodium disilicate Na$_2$O·2SiO$_2$ glass, with the latter being responsible for the high total conductivity previously reported and the mobile defect most likely to be the alkali ion Na$^+$ or K$^+$.

The structurally analogous Sr$_{1-x}$Na$_x$SiO$_{3-x/2}$ (0 < x ≤ 0.45) family also proposed by Singh and Goodenough$^2$ was shown experimentally to exhibit similar behaviour to the Sr$_{0.8}$K$_{0.2}$Si$_{0.5}$Ge$_{0.5}$O$_{2.9}$ materials by Evans et al.$^{12}$ and Bayliss et al.$^{13}$ Furthermore, the latter study theoretically demonstrated the high energetic costs of anion defect formation in the Sr$_{1-x}$Na$_x$SiO$_{3-x}$ composition, suggesting their formation as unlikely.$^{13}$ Further experimental work by Tealdi et al.$^{14}$, Lossila et al.$^{15}$, Huang et al.$^{16,17}$, ourselves,$^{18}$ and ab initio molecular dynamics simulation,$^{19}$ have since suggested this behaviour is true across all analogous structures, both K and Na proposed solid solutions.

The mobility of Na$^+$ has been directly probed through the use of variable temperature $^{23}$Na NMR and spin–lattice relaxation times in the laboratory frame (T$_1$) measurements in Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ and Sr$_{0.6}$Na$_{0.4}$SiO$_{2.8}$ showing conclusively that the Na$^+$ ions are highly mobile.$^{20}$ The $^{23}$Na NMR spectra showed a single broad asymmetric peak which narrows down as the temperature is increased to 350 °C,$^{20}$ as expected for Na$^+$ diffusion in a distribution of local environments such as those found in amorphous compounds such as Na$_2$O·2SiO$_2$, confirming the absence of Na doping in SrSiO$_3$ and that Na was present only in the amorphous phase in any significant proportion. Additionally, a decrease in T$_1$ with increasing temperature was observed, confirming both the Na$^+$ are mobile and their mobility is thermally activated.

It is well known that glasses can crystallise when heated above their glass transition temperature T$_g$ at a speed which depends upon the viscosity of this super-cooled liquid. For Na$_2$O·2SiO$_2$ (T$_g$ = 450 °C)$^{22}$, previous in situ high-temperature NMR experiments have shown that the super-cooled liquid is stable over the course of an NMR experiment up to approximately 700 °C.$^{23,24}$ Both studies have evidenced exchange between the Q$^n$ species (n = 2, 3 and 4) in the
super-cooled liquid by $^{29}$Si NMR while Liu et al.$^{23}$ additionally showed a $^{23}$Na $T_1$ minimum around 530 °C and an associated activation energy of $67 \pm 5$ kJ.mol$^{-1}$, close to measured values for tracer diffusion or electrical conductivity in melts (55 to 75 kJ.mol$^{-1}$).$^{25-30}$ The recent in situ $^{23}$Na NMR investigation by Evans et al.$^{20}$ performed on the mixed Sr$_{0.60}$Na$_{0.40}$SiO$_{2.80}$ composition up to 350 °C yields an activation energy (23 kJ.mol$^{-1}$) close to the 31 kJ.mol$^{-1}$ value obtained by impedance spectroscopy.$^{10}$ This decrease in activation energy is somewhat contradictory with the well described “mixed alkali effect”$^{31}$ and an opposite trend has been observed for the mixed Na/K disilicate system,$^{23}$ hence the importance to rationalize the high temperature $^{23}$Na NMR behaviour.

More recently, Hu et al.$^{32}$ performed a multinuclear solid state NMR investigation in an attempt to determine the structure, chemical composition and ion dynamics of all species in various levels of Na substituted SrSiO$_3$. Interestingly and contrary to most recent work$^{11-14,18,20}$ the authors suggest up to 10 mol% Na substitution is possible on the Sr site in the SrSiO$_3$ lattice, with concentrations above this value causing phase separation to occur and leading to the formation of, to the best of our knowledge, a previously unreported amorphous $\beta$-Na$_2$Si$_2$O$_5$ phase. The proposed phase separation on increasing Na concentration above 10 mol% is unusual and this amongst other issues are addressed in further detail during the main body of this work.

Na$_2$Si$_2$O$_5$ has a complex polymorphism$^{33}$ with a melting point at 874 °C,$^{34}$ and completely devitrifies to form the crystalline $\alpha$-Na$_2$Si$_2$O$_5$ phase above 650 °C for which the XRD patterns$^{35}$ and all $^{17}$O,$^{36,37}$ $^{23}$Na,$^{38-40}$ $^{29}$Si,$^{38,41,42}$ solid state NMR spectra$^{43}$ are known and are uniquely characteristic of this phase, therefore providing an additional pathway for phase identification whether crystalline or amorphous. Additionally, a large range of ionic conductivities have been reported in the literature for Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ from ac impedance data$^{2,10,14,16}$ and may arise from this devitrification process and the thermal history of the sample.
since it was recently postulated by \textit{ab initio} molecular dynamics simulation that while Na$_2$O·2SiO$_2$ glass is a good Na$^+$ conductor, crystalline Na$_2$Si$_2$O$_5$ is an insulator.$^{19}$

In this work, we focus on a complete structural and Na$^+$ ion dynamics solid state NMR study of the proposed sodium strontium silicate fast ion conductors of nominal composition Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ over a wide temperature range that follows our initial investigations.$^{11,13}$ The unique capability of NMR to probe, in both amorphous and crystalline materials, the local structure and ion dynamics in fast ion conductors$^{44,45}$ permits to explain the previous experimental results described above that have been the subject of debates in the literature.$^{1,2,5,6,10-20,32}$ Upon devitrification of Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ at 800 °C, the amorphous Na$_2$O·2SiO$_2$ glassy phase not observed by XRD forms crystalline $\alpha$-Na$_2$Si$_2$O$_5$ as evidence by the XRD data and $^{17}$O, $^{23}$Na and $^{29}$Si NMR spectra fingerprints. Extensive variable temperature $^{23}$Na NMR data including line shape analysis, spin–lattice relaxation rates in the laboratory frame ($T_1^{-1}$) and/or in the rotating frame ($T_1^{-1}$) evolution as a function of temperature provides compelling evidence for the fast and slow Na dynamics in as prepared and devitrified Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$, respectively. These results highlight the fast Na$^+$ transport in amorphous Na$_2$O·2SiO$_2$ glass and its absence in $\alpha$-Na$_2$Si$_2$O$_5$, respectively, and highlight potential for the design of non-crystalline solid state fast ion conductors.

\textbf{Materials and Methods}

Light blue Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ was prepared by solid state synthesis from SrCO$_3$ (Sigma-Aldrich, $>$ 99.9 %), Na$_2$CO$_3$ (Sigma-Aldrich, $>$ 99.9999 %) and SiO$_2$ (Sigma-Aldrich, $>$ 99.9 %) following a literature procedure (thereafter called as prepared).$^2$ The same sample was used throughout this work and previous studies by our groups,$^{13}$ removing any ambiguity in sample composition. The starting materials were mixed in a stoichiometric amount using a mortar and pestle and then heated at 1050 °C for 20 h in air in an Al$_2$O$_3$ crucible, with heating and cooling
rates of 5 °C.min⁻¹. Devitrification of Sr₀.₅₅Na₀.₄₅SiO₂.₇₇₅ was performed by holding the as prepared sample at 800 °C for 4 h (heating and cooling rates of 5 °C.min⁻¹) in air using a Al₂O₃ crucible. Oxygen ¹⁷O enrichment was performed by heating the devitrified Sr₀.₅₅Na₀.₄₅SiO₂.₇₇₅ sample in a Quartz tube under 60 % ¹⁷O enriched ¹⁷O₂ gas (Sigma-Aldrich, used as received) at 750 °C in a tube furnace for 24 h (heating and cooling rates of 5 °C.min⁻¹).

XRD patterns were obtained on a PANalytical X’Pert Pro diffractometer using the CoKα radiation of wavelength 1.79 Å. A layer of powder was put on a thin layer of grease spread onto the surface of a glass disk which was used as the sample holder. Rietveld refinements of the data were performed using EXPGUI⁴⁶ and GSAS.⁴⁷ Crystallographic information files (CIF) were used as starting models for the structural refinements, obtained from the Inorganic Crystal Structure Database (ICSD). During the refinements, the background, lattice cell parameters, zero point error and atomic positions for Sr and Si were refined. The atomic displacement parameters (ADP) were fixed as equivalent for each atomic species and allowed to refine.

¹⁷O, ²³Na and ²⁹Si solid state NMR experiments were performed on a 9.4 T Bruker Avance III HD 400 MHz spectrometer equipped with a Bruker 4 mm HXY Magic Angle Spinning (MAS) probe (in double resonance mode) or a Bruker 4 mm HX MAS high temperature probe (for variable temperature experiments). Additional high temperature ²³Na NMR experiments above 360 °C were carried out on a 9.4 T Bruker Avance spectrometer using a single channel static liquid state NMR probe and a homemade CO₂ laser (λ = 10.6 μm, 250 W) heating system developed in Orléans (CNRS – CEMHTI).⁴⁸,⁴⁹ The sample is placed inside a boron nitride BN crucible (chemically inert to Sr₀.₅₅Na₀.₄₅SiO₂.₇₇₅ at high temperature, see XRD data and text) and is heated by 2 laser beams passing axially through the NMR probe, irradiating the top and bottom of the BN crucible to ensure temperature homogeneity. A flow of air is used for thermal shielding and cooling of the radio frequency coil and an Ar stream prevents oxidation of the BN crucible at high temperature. One dimensional ¹⁷O NMR spectra were
obtained at a MAS frequency of 13 kHz with a rotor synchronised Hahn echo $90 - \tau - 180 - \tau - \text{acq}$ sequence with a delay $\tau$ of 77 $\mu$s (1 rotor period) and using solid 90 degree pulse of 1.2 $\mu$s at a rf field amplitude of 70 kHz. One dimensional $^{23}\text{Na}$ static NMR spectra were also obtained with an echo sequence ($\tau = 30 \mu$s). $^{23}\text{Na}$ MAS NMR spectra were obtained at a MAS frequency of 10 kHz with a one pulse sequence. All $^{23}\text{Na}$ 90 degree pulse were of 1.5 $\mu$s at a rf field amplitude of 83 kHz on the MAS probe and of 13 $\mu$s at a rf field amplitude of 9.6 kHz on the static laser probe (unless otherwise specified). The one dimensional $^{29}\text{Si}$ NMR spectra were obtained at a MAS frequency of 10 kHz with a one pulse sequence using 90 degree pulse of 5 $\mu$s at a rf field amplitude of 50 kHz.

Spin–lattice relaxation times $T_1$ in the laboratory frame were recorded under static conditions and at $v_0(^{23}\text{Na}) = 105.8$ MHz with a saturation recovery pulse sequence, and were fitted to a single stretched exponential of the form $1 - \exp[-(\tau/T_1)^\alpha]$ (where $\tau$ are variable delays and $\alpha$ the stretched exponential factor). For the as prepared Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ sample due to the onset of crystallization of the Na$_2$O$2$SiO$_2$ glass into crystalline $\alpha$-Na$_2$Si$_2$O$_5$ across the crystallisation phase transition temperatures $T_c$s (490 – 650 °C) which have very different $T_1$s, the data were fitted with a double stretched exponential of the form $1 - \exp[-(\tau/T_{1(1)})^\alpha] + 1 - \exp[-(\tau/T_{1(2)})^\beta]$ (where $T_{1(1)}$ and $T_{1(2)}$ are the different spin–lattice relaxation times), and follow a similar approach used previously on Na$_2$O$2$SiO$_2$ glass around 635 – 699 °C.$^{23}$ Spin–lattice relaxation times $T_1$, in the rotating frame were obtained under static condition with a spin lock sequence at frequencies of $v_1(^{23}\text{Na}) \approx 20$ and 35 kHz on the 4 mm HX MAS high temperature NMR probe, and at $\approx 6.7$ and 9.6 kHz on the static laser probe, the data obtained fitted to a single stretched exponential. Temperature calibration of the 4 mm HX MAS high temperature NMR probe was performed using the $^{207}\text{Pb}$ NMR resonance of Pb(NO$_3$)$_2$, the $^{63}\text{Cu}$ resonances of Cu$^1$Br across the $\gamma$-to-$\beta$ phase transition at 385 °C and of Cu$^1$I across the $\gamma$-to-$\beta$
phase transition at 369 °C, while temperature calibration of the static laser probe was obtained by the direct measurement of the melting points of reference samples. The sample temperatures quoted subsequently have all been corrected according to this calibration, and have an accuracy of approximately ± 10 °C (between room temperature and 150 °C), ± 20 °C (between 150 °C and 360 °C) and ± 15 °C (above 360 °C on the static laser probe).

High field $^{17}$O and $^{23}$Na solid state NMR experiments were performed on a 20 T Bruker Avance II 850 MHz spectrometer using Bruker 3.2 mm HXY MAS probe (in double resonance mode) and Bruker 2.5 mm HX MAS probe, respectively. The one dimensional $^{17}$O NMR spectrum was obtained at a MAS frequency of 22 kHz with a rotor synchronised Hahn echo sequence (1 rotor period) using solid 90° degree pulse of 1 µs at a rf field amplitude of 83 kHz. One dimensional $^{23}$Na NMR spectra were obtained at a MAS frequency of 30 kHz with a one pulse sequence using solid 90 degree pulse of 1.25 µs at a rf field amplitude of 100 kHz.

All $^{17}$O, $^{23}$Na and $^{29}$Si shifts were externally referenced to H$_2$O, 1 M NaCl in H$_2$O and Si(CH$_4$)$_3$ at 0 ppm, respectively.

**Results and Discussions**

**Phase identification with XRD**

A sample of nominal composition Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ was obtained by solid state synthesis using a known procedure involving heating at 1050 °C in air (cooling and heating rates of 5 °C.min$^{-1}$). The XRD pattern of Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ (Figure 1a) was refined in space group C2/c with lattice cell parameters and atomic coordinates matching the expected ones from the previous neutron diffraction investigation and crystalline α-SrSiO$_3$ (ICSD n° 59308). As before, no other peaks than α-SrSiO$_3$ were observed in Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$. However, in the devitrified Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ sample an additional set of reflections corresponding to α-
Na$_2$Si$_2$O$_5$ (ICSD n° 34669) are clearly visible and were refined by Rietveld giving acceptable quality of fit values (low tick marks Figure 1b).

![Figure 1a](image1.png)

![Figure 1b](image2.png)

Figure 1. Rietveld refinements of XRD data of (a) Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ and (b) devitrified Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$. The results clearly show that the material is two phase in nature which agrees with previous work.$^{12-14}$ The crystalline phases present are $\alpha$-SrSiO$_3$ (ICSD n° 59308)$^{54}$ and $\alpha$-Na$_2$Si$_2$O$_5$ (ICSD n° 34669)$^{35}$ (lower tick marks in b).
Phase identification with multinuclear $^{29}\text{Si}$, $^{23}\text{Na}$ and $^{17}\text{O}$ NMR spectroscopy

The $^{29}\text{Si}$ NMR spectrum of Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ is given in Figure 2a and shows a sharp resonance at $-84.8$ ppm in addition to broad signals between $-77$ ppm and $-99$ ppm, as observed by Evans et al.$^{12}$ and Tealdi et al.$^{14}$ The sharp line is typical of a crystalline phase (as also evidenced by the long T$_1$ relaxation time of $^{29}\text{Si}$ estimated around 60 min) and is assigned to $\alpha$-SrSiO$_3$ based on its shift.$^{55}$ The broad line and its short T$_1$ relaxation time (0.2 s) reflect the presence of an amorphous phase identified as sodium disilicate Na$_2$O2SiO$_2$ glass by previous quantification of the XRD patterns$^{11}$ and comparison with the known $^{29}\text{Si}$ MAS spectrum of this Na$_2$O2SiO$_2$ glass reported by Stebbins et al.$^{56}$ which shows three broad and Gaussian signals resonating at $-77$, $-88$ and $-99$ ppm and corresponding to Q$^2$, Q$^3$ and Q$^4$ units.

The $^{29}\text{Si}$ NMR spectrum of devitrified Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ (Figure 2b) also reveals the presence of the same sharp signal at $-84.8$ ppm ($\alpha$-SrSiO$_3$). However, the broad signals of Na$_2$O2SiO$_2$ glass in Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ have now completely disappeared and have been replaced by a sharp signal at $-94.3$ ppm (with a long T$_1$ of approximately 100 min) assigned to crystalline $\alpha$-Na$_2$Si$_2$O$_5$ phase.$^{38,41,42}$ This observation agrees well with the devitrification of Na$_2$O2SiO$_2$ glass under the heat treatment condition used (800 °C and 1 bar)$^{33}$ to devitrified Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ from the as prepared Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$. A related $^{29}\text{Si}$ NMR spectrum of a devitrified Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ sample at 650 °C was previously observed,$^{14}$ although it shows the presence of three unexplained additional $^{29}\text{Si}$ resonances between $-87$ and $-92$ ppm which could actually be assigned to $\beta$-Na$_2$Si$_2$O$_5$ (two Q$^3$ Si environments at $-86.7$ and $-88.6$ ppm)$^{38,39}$ and $\gamma$-Na$_2$Si$_2$O$_5$ (one Q$^3$ Si environments at $-90.4$ ppm),$^{38}$ two other known polymorphs of Na$_2$Si$_2$O$_5$.$^{33}$
Figure 2. $^{29}$Si MAS NMR spectra of (a) $\text{Sr}_{0.55}\text{Na}_{0.45}\text{SiO}_{2.775}$ and (b) devitrified $\text{Sr}_{0.55}\text{Na}_{0.45}\text{SiO}_{2.775}$ obtained at 9.4 T. Dashed lines represent line shape simulation and deconvolution of the three Q2, Q3 and Q4 units of the Na$_2$O-2SiO$_2$ glass.

The $^{23}$Na MAS NMR spectrum (Figure 3) of $\text{Sr}_{0.55}\text{Na}_{0.45}\text{SiO}_{2.775}$ obtained at 9.4 T shows a broad line shape with a tail at low frequency, similar to Na$_2$O-2SiO$_2$ glass$^{57}$ and the recent work on $\text{Sr}_{0.6}\text{Na}_{0.4}\text{SiO}_{2.8}$.$^{20}$ The tail results from a distribution of quadrupolar couplings$^{58}$ and indicates the presence of significant structural disorder and a range of Na sites (also corroborated by the short T$_1$ time measured of 98 ± 11 ms). All these observations are therefore in agreement with the presence of an amorphous Na-containing glass in $\text{Sr}_{0.55}\text{Na}_{0.45}\text{SiO}_{2.775}$. A MAS spectrum recorded at a higher field of 20 T yields a narrower line, as anticipated,$^{59}$ nevertheless no additional Na site is observed as is commonly observed in glasses.

In contrast to $\text{Sr}_{0.55}\text{Na}_{0.45}\text{SiO}_{2.775}$, devitrified $\text{Sr}_{0.55}\text{Na}_{0.45}\text{SiO}_{2.775}$ shows the typical $^{23}$Na second order line shape of $\alpha$-Na$_2$Si$_2$O$_5$,$^{38}$ reinforcing that this phase is formed upon devitrification of the Na$_2$O-2SiO$_2$ glass. More importantly, it also shows that Na is only present as Na$_2$O-2SiO$_2$ glass in $\text{Sr}_{0.55}\text{Na}_{0.45}\text{SiO}_{2.775}$ and confirms the absence of Na doping in SrSiO$_3$ suggested before.$^{11-14,18,20}$
Figure 3. $^{23}$Na MAS NMR spectra of (a) Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ and (b) devitrified Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ obtained at 9.4 and 20 T. Stars (*) and dash (#) indicate spinning sidebands and the outer satellite transition. Dashed lines represent the line shape simulation using the known NMR parameters for $\alpha$-Na$_2$Si$_2$O$_5$ (isotropic chemical shift $\delta_{\text{iso, cs}}$ = 17.4 ppm, quadrupolar coupling constant $C_Q = 1.82$ MHz and asymmetry parameter $\eta_Q = 1.0$).$^{38}$ Note that these line shapes are offset from $\delta_{\text{iso, cs}}$ by the isotropic second-order quadrupolar shift $\delta_{\text{iso, Q}}$ ($\delta_{\text{iso, Q}} = 9.9$ ppm and 2.2 ppm at 9.4 and 20 T, respectively) which varies inversely with the square of the strength of the magnetic field.$^{59}$

Figure S1 presents the $^{17}$O MAS NMR spectra $^{17}$O enriched devitrified Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ (prepared by gas solid exchange with $^{17}$O enriched O$_2$ gas)$^{60}$ and reveals a
range of broad signals between 75 and –150 ppm (at 9.4 T) along with a weak low field signal around 94 ppm. Hu et al.\textsuperscript{32} assigned the high field NMR signals (from 75 to –150 ppm) to an amorphous Na\textsubscript{2}Si\textsubscript{2}O\textsubscript{5} phase, however these resonances undoubtedly appear at the shifts anticipated for all three oxygen sites expected in \(\alpha\)-Na\textsubscript{2}Si\textsubscript{2}O\textsubscript{5}\textsuperscript{36} as Figure S1 demonstrates. The low field 94 ppm signals correspond very well with the position of the non-bridging oxygens O1 and O2 in \(\alpha\)-SrSiO\textsubscript{3} and we note that the NMR signal of the bridging oxygen O3 in \(\alpha\)-SrSiO\textsubscript{3} overlaps with the ones of \(\alpha\)-Na\textsubscript{2}Si\textsubscript{2}O\textsubscript{5}.

\textit{Na ion mobility: \(^{23}\text{Na} NMR spectra line shape analysis}}

The room temperature \(^{23}\text{Na}\) static NMR spectra of Sr\textsubscript{0.55}Na\textsubscript{0.45}SiO\textsubscript{2.75} is asymmetrically broadened (Figure 4a) as observed before\textsuperscript{20} and corresponds to the amorphous Na\textsubscript{2}O2SiO\textsubscript{2} glassy phase. Upon increasing the sample temperature to approximately 340 °C (using a standard solid-state NMR probe and N\textsubscript{2} gas as heat carrier), the \(^{23}\text{Na}\) NMR lines narrow and yield a symmetric NMR line shape centred at –21 ppm (Figures 4), in agreement with previous initial experimental work on Sr\textsubscript{0.6}Na\textsubscript{0.4}SiO\textsubscript{2.8},\textsuperscript{20} as well as Na\textsubscript{2}O2SiO\textsubscript{2} and K\textsubscript{2}O2SiO\textsubscript{2} disilicates,\textsuperscript{23} and confirmed computationaly,\textsuperscript{19} which demonstrate that the Na\textsubscript{2}O2SiO\textsubscript{2} glass is a fast Na ion conductor. The temperature evolution of the \(^{23}\text{Na}\) line width \(\nu\) and peak maxima position \(\delta_{\text{max}}\) have been plotted in Figure 5 to give an overall indication of the line narrowing and change in \(\delta_{\text{max}}\) with temperature, however the full analysis of the change in quadrupolar line shape with temperature results from a complex combination of 2\textsuperscript{nd} order effects and dynamical shifts which are beyond the scope of this work.
Figure 4. Representative high temperature $^{23}$Na static NMR spectra of (a) $\text{Sr}_{0.55}\text{Na}_{0.45}\text{SiO}_{2.775}$ and (b) devitrified $\text{Sr}_{0.55}\text{Na}_{0.45}\text{SiO}_{2.775}$ obtained at 9.4 T on a standard NMR probe. The horizontal scaling factors are given on the right hand side of the spectra. Dashed lines represent line shape simulation using the NMR parameters of $\alpha$-$\text{Na}_2\text{Si}_2\text{O}_5$.\(^{38}\)

Unlike $\text{Sr}_{0.55}\text{Na}_{0.45}\text{SiO}_{2.775}$, the $^{23}$Na static NMR line shape of the devitrified $\text{Sr}_{0.55}\text{Na}_{0.45}\text{SiO}_{2.775}$ material (Figure 4b) remains broad and is virtually unchanged (Figure 5a) as the temperature is increased to 360 °C, the integral of the spectra decreasing due to unfavourable Boltzmann distribution at high temperature. The lack of change in line shape is a clear indication
of the absence of Na ion dynamics and poor Na ion mobility as expected in α-Na$_2$Si$_2$O$_5$ and as determined by both its low conductivity$^{16}$ and the small atomic displacements computed by \textit{ab initio} molecular dynamics simulation.$^{19}$

![Figure 5](image)

Figure 5. Temperature dependence of the (a) $^{23}$Na NMR central transition line width $\nu$ (taken as full width at half-maximum) and (b) $^{23}$Na peak position maxima $\delta_{\text{max}}$ of Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ (blue circles) and devitrified Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ (red circles) materials. Data were measured at a Larmor frequency of $\nu_0 = 105.8$ MHz. The glass transition temperature $T_g$ of Na$_2$O:2SiO$_2$ glass (450 °C) and the melting point $T_m$ of crystalline α-Na$_2$Si$_2$O$_5$ phase (874 °C) are given in the figure.

Additional high temperature static NMR experiments were performed on both Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ materials on a static NMR probe and a homemade CO$_2$ laser ($\lambda = 10.6$ µm, 250 W) heating system developed in Orléans (CNRS – CEMHTI)$^{48,49}$ to probe further the Na diffusion and \textit{in situ} crystallisation behaviours (Figure 6). The width of $^{23}$Na static NMR spectra of Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ (Figure 6a) decreases from room temperature to 358 – 412 °C then
broadens significantly at 529 °C. This broadening is due to a phase transition and the crystallisation of the amorphous Na$_2$O2SiO$_2$ glassy phase into crystalline $\alpha$-Na$_2$Si$_2$O$_5$, a process that was surprisingly found to have multiple crystallisation phase transition temperatures $T_c$. Crystallisation starts to occur at 490 °C and peaks at 550 and 650 °C as determined by differential scanning calorimetry (DSC) and was observed in in situ high temperature XRD and by $^{29}$Si MAS NMR spectroscopy during the devitrification of Na$_2$O2SiO$_2$ glass. These results are in contrast with the in situ high temperature $^{29}$Si NMR study of pure Na$_2$O2SiO$_2$ glass that shows the presence of a supercooled liquid phase up to about 200 °C above the $T_g$ (450 °C) and no crystallisation of $\alpha$-Na$_2$Si$_2$O$_5$. The presence of crystalline $\alpha$-SrSiO$_3$ in Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ therefore dramatically changes the thermal behaviour of the Na$_2$O2SiO$_2$ glass present in the mixture by acting as seeds of the heterogeneous crystallisation.

As the temperature is increased further, the $^{23}$Na line shape of Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ remains largely unchanged up to 845 °C with a slight shift of the resonances towards higher frequencies (see Figure 6b). At and above 901 °C, a much narrower Lorentzian line (full width at half maximum around 1 kHz) is observed indicative of a melted sample, in agreement with the known melting point $T_m$ of $\alpha$-Na$_2$Si$_2$O$_5$ (874 °C) and visual inspection of the sample at room temperature after the high temperature NMR experiments. These experimental observations are also corroborated by in situ $^{23}$Na two-dimensional quadrupole nutation NMR spectroscopy data that shows the non-selective central transition regime above $T_m$ characteristic of liquid sample. Upon quenching of Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ from 934 °C to room temperature (in approximately 20 s) by turning off the laser suddenly, all $^{23}$Na and $^{29}$Si NMR data (Figures S3-4) and XRD pattern (Figure S2b) are consistent with the as prepared Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ showing the presence of crystalline $\alpha$-SrSiO$_3$ and the amorphous Na$_2$O2SiO$_2$ glassy phase. The XRD data also shows that no reaction is observed between the BN crucible and the Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ phase under the reductive condition used with the laser NMR probe.

Figure 6. Representative very high temperature $^{23}$Na static NMR spectra of (a) Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ and (b) devitrified Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ obtained at 9.4 T on a static laser NMR probe.$^{48,49}$ In (a), 4 times more transients were acquired for the $^{23}$Na NMR data collected at and above 782 °C. In (b), 8 times more transients were acquired for the $^{23}$Na NMR data collected at and above 649 °C. $^{23}$Na spectra at and above 901 °C were obtained with a $\pi/2$ pulse length of 26 µs under the non-selective central transition regime (except at 901 °C in (b)). The crystallisation phase transition temperatures $T_c$ of 490, 550 and 650 °C and the melting point $T_m$ of 874 °C of α-Na$_2$Si$_2$O$_5$ are given in the figure. The horizontal scaling factors are given on the right hand side of the spectra. Dashed lines represent line shape simulation using the NMR parameters of α-Na$_2$Si$_2$O$_5$.$^{38}$

The $^{23}$Na static NMR spectra of devitrified Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ given in Figure 6b is unchanged up to heating at 412 °C. Above this temperature, a change in line shape is observed. The change may be associated with some Na dynamics in α-Na$_2$Si$_2$O$_5$, or, even more likely, additional phase transitions in α-Na$_2$Si$_2$O$_5$, given the existence of a α''-Na$_2$Si$_2$O$_5$ phase below 678 °C, α'-Na$_2$Si$_2$O$_5$ between 678 and 707 °C, and α-α$_2$Si$_2$O$_5$ above 707 °C, corresponding to small distortions of the SiO$_4$ groups.$^{33}$ Further heating of the devitrified Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ sample to 934 °C yields significant line narrowing of the $^{23}$Na NMR spectrum, a Lorentzian line shape and a non-selective central transition regime, all consistent with melting of α-Na$_2$Si$_2$O$_5$ ($T_m$ of 874 °C). Melting should have happened at the quoted static laser temperature of 901 °C (first temperature recorded above $T_m$), however the estimated probe temperature accuracy is around 30 °C in this high temperature range (see Experimental Section),$^{48,49}$ explaining the slight discrepancy. Additionally, it is likely that the rate of crystallisation is slow or that the $T_m$ of α-Na$_2$Si$_2$O$_5$ in the presence of solid α-SrSiO$_3$ differs from the one of pure α-Na$_2$Si$_2$O$_5$.$^{33}$
Quenching of the devitrified Sr\(_{0.55}\)Na\(_{0.45}\)SiO\(_{2.775}\) melt from 934 °C to room temperature largely regenerates the as prepared Sr\(_{0.55}\)Na\(_{0.45}\)SiO\(_{2.775}\) phase with crystalline \(\alpha\)-SrSiO\(_3\) and amorphous Na\(_2\)O·2SiO\(_2\) glassy phase detected by \(^{23}\)Na/\(^{29}\)Si NMR and XRD (Figures S2c, S3-S4). More specifically, the \(^{29}\)Si MAS NMR spectrum (Figure S4) displays the sharp resonance at –84.8 ppm associated with \(\alpha\)-SrSiO\(_3\) and a broad resonance consistent with an amorphous phase, and the absence of the sharp signal at –94.3 ppm associated with \(\alpha\)-Na\(_2\)Si\(_2\)O\(_5\) (Figure 2) in agreement with the XRD pattern (Figure S2c) only revealing \(\alpha\)-SrSiO\(_3\) as the crystalline phase. The \(^{23}\)Na static NMR spectrum (Figure S3) of this quenched material also shows a broad and featureless asymmetric peak rather than the second-order line shape of \(\alpha\)-Na\(_2\)Si\(_2\)O\(_5\) (Figures 6 and 8).

Comparison between the \(^{23}\)Na static NMR spectra of both melts at 934 °C (Figure S5) obtained from the as prepared and devitrified Sr\(_{0.55}\)Na\(_{0.45}\)SiO\(_{2.775}\) materials shows very good overlap, confirming that the only Na-containing compound in the molten state is liquid Na\(_2\)Si\(_2\)O\(_5\).

**Na ion mobility:** \(^{23}\)Na spin lattice relaxation rates

Probing dynamics and ionic motion could also be achieved from measuring the \(T_1\) and/or \(T_1\rho\) rates and yield correlation times on the order of the Larmor frequency (~ 10\(^8\) Hz) and spin lock frequency (~ 10\(^3\) Hz).\(^{61,62}\) The determination of the \(T_1\) and/or \(T_1\rho\) rates has, for example, enabled the understanding of the Li ion diffusion processes and its quantification (jump rates, activation energies) in a range of fast lithium ion conductors using \(^7\)Li NMR.\(^{45,63-66}\) A similar approach is used here with \(^{23}\)Na NMR to shed the light on the sodium dynamics in both Sr\(_{0.55}\)Na\(_{0.45}\)SiO\(_{2.775}\) and devitrified Sr\(_{0.55}\)Na\(_{0.45}\)SiO\(_{2.775}\) and to obtain quantitative information on the sodium mobility over a range of time scales and up to the melting point of Na\(_2\)Si\(_2\)O\(_5\) (874 °C). The results complement the preliminary \(^{23}\)Na \(T_1\) investigation recently reported on Sr\(_{0.6}\)Na\(_{0.4}\)SiO\(_{2.8}\) that were limited to temperatures from RT to 150 °C.\(^{20}\) Figure 7 plots the
variable temperature $^{23}\text{Na} \ T_1^{-1}$ and $T_{1\rho}^{-1}$ rates of $\text{Sr}_{0.55}\text{Na}_{0.45}\text{SiO}_{2.775}$ from room temperature to 934 °C, above the melting point of the Na-containing phase $\alpha$-Na$_2$Si$_2$O$_5$. As the temperature is increased from room temperature to approximately the first crystallization temperature $T_c$ of the Na$_2$O2SiO$_2$ glassy phase (490 °C), the $T_1^{-1}$ and $T_{1\rho}^{-1}$ values increased, indicating a slow motional regime (characterised by $2\pi\nu_0\tau_c > 1$ and $2\pi\nu_1\tau_c > 1$, respectively where $\nu_0$, $\nu_1$ and $\tau_c$ are the $^{23}\text{Na}$ Larmor frequency, the spin lock frequency and the correlation times of the motion)\textsuperscript{61,62} and that the $T_{1(\rho)}^{-1}$ rates are sensitive to local site-to-site hopping. The data clearly follows an Arrhenius behaviour highlighting that the relaxation data indeed probes a thermally activated process. Activation energy values for the short range Na diffusion process of $28 \pm 2$ kJ.mol$^{-1}$ (from $T_1^{-1}$) and $\sim 22 \pm 2$ kJ.mol$^{-1}$ (from $T_{1\rho}^{-1}$ above 160 °C) could be extracted.

Upon increasing the temperature further across the various $T_c$ (490 – 650 °C) of the Na$_2$O2SiO$_2$ glass, a short and a long $T_1$ (plotted as light and dark blue in Figure 12, respectively) are required to fit the $^{23}\text{Na}$ saturation recovery experiments (see Experimental Section for details) of $\text{Sr}_{0.55}\text{Na}_{0.45}\text{SiO}_{2.775}$. The need for two $T_1$ values reflects a transition region with the onset of crystallisation of Na$_2$O2SiO$_2$ (short $T_1$) and the additional presence of the $\alpha$-Na$_2$Si$_2$O$_5$ phase (long $T_1$) in $\text{Sr}_{0.55}\text{Na}_{0.45}\text{SiO}_{2.775}$. A single $T_1$, value fits accurately the $^{23}\text{Na}$ spin lock experiments, however it is likely that the value obtained is an averaged $T_1$, and echoes the fact that both Na$_2$O2SiO$_2$ glass and crystalline $\alpha$-Na$_2$Si$_2$O$_5$ phases exist in $\text{Sr}_{0.55}\text{Na}_{0.45}\text{SiO}_{2.775}$ at these temperatures. The long $^{23}\text{Na} \ T_1^{-1}$ values (dark blue) start to level off (as observed around the $T_g$ of the Na$_2$O2SiO$_2$ glass)\textsuperscript{23} and a change in activation is observed (estimated to $\sim 10 \pm 3$ kJ.mol$^{-1}$) in the 490 – 650 °C temperature range. Meanwhile the short $^{23}\text{Na} \ T_1^{-1}$ values (light blue) are of the same order of magnitude than for $\alpha$-Na$_2$Si$_2$O$_5$ in devitrified $\text{Sr}_{0.55}\text{Na}_{0.45}\text{SiO}_{2.775}$ (red in Figure 7 - see below). Above 490 – 650 °C, $\alpha$-Na$_2$Si$_2$O$_5$ is the only Na-containing phase and an Arrhenius plot of $^{23}\text{Na} \ T_1^{-1}$ from 650 °C to $\sim T_m$ (874 °C) yields a large activation value of $123 \pm 9$ kJ.mol$^{-1}$ (and similar to the one obtained for $\alpha$-Na$_2$Si$_2$O$_5$ in devitrified
Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ - see below). Concomitantly, the measured $^{23}$Na $T_1^{-1}$ values decreases (green) and converges towards the ones obtained for $\alpha$-Na$_2$Si$_2$O$_5$ (red/orange).

We note that the apparent $T_{1_\rho}^{-1}$ maxima observed here around 490 – 650 °C are not representative of the $2\pi \nu_0 \tau_c \sim 1$ and $2\pi \nu_1 \tau_c \sim 0.5$ conditions observed in maxima of $T_{1_\rho}^{-1}$ in Arrhenius plot of thermally activated processes.$^{61,62}$ Rather, the maxima correspond to changes occurring in Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ with temperature and the crystallisation of Na$_2$O 2SiO$_2$ glass into $\alpha$-Na$_2$Si$_2$O$_5$ which have short and long $T_{1_\rho}$ values, respectively. Hence, the decrease of $T_{1_\rho}^{-1}$ values with increasing temperature does not probe the fast motional regime (where the relationships $2\pi \nu_0 \tau_c << 1$ and $2\pi \nu_1 \tau_c << 1$ hold). This regime is not accessible here and therefore the $T_{1_\rho}^{-1}$ rates do not access the long range Na diffusion in Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ and Na$_2$O 2SiO$_2$ glass.
Figure 7. Arrhenius plot of the $^{23}$Na spin lattice relaxation rates $T_1^{-1}$ obtained in the laboratory frame at $\nu_0(^{23}$Na) = 105.8 MHz and spin lattice relaxation rates $T_1^{\rho}^{-1}$ obtained in the rotating frame at $\nu_{1}^{(23}$Na) = 6.7, 9.6, 20 and 35 kHz. Data for Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ and devitrified Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ (α-SrSiO$_3$ + α-Na$_2$Si$_2$O$_5$).
Sr_{0.55}Na_{0.45}SiO_{2.775} are shown in blue/green and red/orange circles, respectively. The crystallisation phase transition temperatures $T_c$ of Na$_2$O$_2$SiO$_2$ (490, 550 and 650 °C) and the melting point $T_m$ of crystalline $\alpha$-Na$_2$Si$_2$O$_5$ (874 °C) are given in the figure. Error bars are smaller than symbol sizes.

Table 1 compares the activation energies obtained above with the ones obtained with ac impedance$^{2,10,14,16}$ and the previous $^{23}$Na $T_1^{-1}$ work.$^{20}$ A large range of activation energies ($\sim 17 – 75$ kJ.mol$^{-1}$) has been obtained using ac impedance spectroscopy under comparable temperature range. These discrepancies probably reflect large changes in the actual sample composition of Sr$_{0.55}$Na$_{0.45}$SiO$_{2.77}$ and for example the presence or absence of crystalline Na$_2$Si$_2$O$_5$ and/or Na$_2$O$_2$SiO$_2$ glass depending on the thermal history of the sample, both materials having very different Na ion conductivity properties.$^{16,19}$ The activation energy of 28 kJ.mol$^{-1}$ obtained $T_1^{-1}$ rates over the 22 – 490 °C temperature range compares well with the initial activation energy determined by ac impedance for Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ material (31 kJ.mol$^{-1}$),$^{10}$ although we note that this value was obtained at higher temperature and above the $T_g$ of the Na$_2$O$_2$SiO$_2$ glass (Table 1). The value of 28 kJ.mol$^{-1}$ underestimates the ones obtained in a range of ac impedance studies (46 – 75 kJ.mol$^{-1}$) as often observed while monitoring ionic mobility using both techniques.$^{20,44,67}$ The lower activation energy obtained from NMR versus impedance is ascribed to the fact that a mobile ion has a greater probability to jump back to its original position rather than to a new site, and while ac impedance probes long range bulk mobility, the slow motional regime ($2\pi v_0\tau_c \gg 1$) of the $^{23}$Na NMR data detected here is being sensitive to local dynamics and short diffusion including unsuccessful jumps.$^{45,44}$
Table 1. Comparison between the activation energies of sodium mobility in Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$, Na$_2$O2SiO$_2$ glass, devitrified Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ and crystalline Na$_2$Si$_2$O$_5$ materials.

*Na$_2$O2SiO$_2$ glass sample obtained from slow cooling from 475 °C (above $T_g$) to room temperature and may be partially crystalline.\(^{28}\) Probably the $\alpha$-Na$_2$Si$_2$O$_5$ phase although not stated.

The activation energy value determined above from $^{23}$Na $T_{1-1}$ relaxation data should also be compared with the values available in the literature for pure Na$_2$O2SiO$_2$. The activation energies for Na diffusion obtained below $T_g$ using a range of experimental approaches ($^{22}$Na/$^{24}$Na tracer diffusion,\(^{26,28,29}\) electrical conductivity,\(^{26}\) ac impedance\(^{16,27}\) and $^{23}$Na NMR $T_{1-1}$ data\(^{23}\)) are in relatively good agreement with each other (63 – 84 kJ.mol$^{-1}$, see Table 1). In particular that the value obtained from $^{23}$Na NMR $T_{1-1}$ data\(^{23}\) (67 ± 5 kJ.mol$^{-1}$)\(^{23}\) fits well into this range. However, we also note that a more recent $ab$ initio molecular dynamics study deviates significantly from these observations (with activation energies of 16 and 29 kJ.mol$^{-1}$).
between below and above $T_g$, respectively) and is most likely explained by the short simulation time used (40 ps) for the mean square displacement and the relative small size of the cell used (144 atoms).\textsuperscript{11} The shorter Na$^+$ diffusion activation energies derived here for Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ are therefore much smaller than the ones experimentally obtained for pure Na$_2$O·2SiO$_2$ glass, indicating that the presence of crystalline $\alpha$-SrSiO$_3$ dramatically changes the Na$^+$ diffusion behaviour of the Na$_2$O·2SiO$_2$ glass.

Figure 7 also plots the behaviour of T$_1^{-1}$ rates versus temperature in the devitrified Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$. As expected the T$_1$ values in this material are much longer (hence short T$_1^{-1}$) than the ones of as prepared Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ due to the presence of the crystalline $\alpha$-Na$_2$Si$_2$O$_5$ phase. However, and in contrast to Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$, at temperature below 450 °C, the T$_1^{-1}$ rates of devitrified Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ are largely temperature independent and simply probe atomic vibration. Over the same temperature range, long T$_1$ values are anticipated (longer than T$_1$, $\sim$ 82 ms obtained at 412 °C with $v_1 = 9.6$ kHz) and could not be obtained due to limitation on the radio frequency capabilities of the liquid state NMR probe used in the high temperature setup.\textsuperscript{48,49} Around 550 °C, a kink is clearly observed in the T$_1^{-1}$ plot and both T$_1^{-1}$ and T$_1^{-1}$ rates increased quickly and follow Arrhenius behaviour from which the large activation energy values (148 ± 14 kJ.mol$^{-1}$ and $\sim$ 56 ± 5 kJ.mol$^{-1}$, respectively) demonstrate the poor Na ion mobility of the $\alpha$-Na$_2$Si$_2$O$_5$ phase, supporting the recent ab initio molecular dynamics simulations on crystalline Na$_2$Si$_2$O$_5$.\textsuperscript{11} Similar T$_{1(\rho)}$ values and activation energies (123 ± 9 kJ.mol$^{-1}$ from T$_1^{-1}$ and $\sim$ 68 ± 11 kJ.mol$^{-1}$ from T$_\rho^{-1}$) were obtained in Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ above T$_g$s as the sample composition ($\alpha$-Na$_2$Si$_2$O$_5$ and $\alpha$-SrSiO$_3$) is identical to the one of devitrified Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$.
Conclusions

In summary, the present multinuclear NMR study provides extensive evidence for the absence of Na doping in strontium silicate $\alpha$-SrSiO$_3$ and the multiphasic nature of this Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ material. The NMR data indicate that this phase is made of a mixture of crystalline $\alpha$-SrSiO$_3$, clearly identified by its narrow $^{29}$Si linewidth and chemical shift, and an amorphous glassy phase of composition Na$_2$O2SiO$_2$, as evidenced by the detection of a single broad and featureless peak in both $^{23}$Na and $^{29}$Si NMR spectra. High temperature treatment of Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ at 800 °C, just below the melting point of its Na$_2$O2SiO$_2$ glass component (874 °C) followed by slow cooling to room temperature, devitrifies the Na$_2$O2SiO$_2$ glass. The XRD pattern of the resulting Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ phase indicates the presence of additional reflections to $\alpha$-SrSiO$_3$, which could be structurally refined to crystalline $\alpha$-Na$_2$Si$_2$O$_5$. Comparison between all the $^{17}$O, $^{23}$Na and $^{29}$Si NMR data recorded on devitrified Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ with the ones known for this $\alpha$-Na$_2$Si$_2$O$_5$ phase confirms its presence as the sole Na-containing material.

The high ionic conductivity in Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ originally attributed to the diffusion of oxide ions, and questioned quickly in the literature, is in fact due to the high sodium ion mobility observed in the Na$_2$O2SiO$_2$ glass. Extensive variable temperature $^{23}$Na NMR experiments from room temperature to below the $T_g$ of the Na$_2$O2SiO$_2$ glass (450 °C) reveals a clear line narrowing of the $^{23}$Na line shape, resulting from the mobility of sodium ions, and an evident temperature dependency of the spin lattice relaxation rates $T_{1(\rho)}^{-1}$ corresponding to a thermally activated diffusion process with an activation energy in the 22 – 28 kJ.mol$^{-1}$ range. The same $^{23}$Na NMR experiments carried out on devitrified Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ distinctively showed the absence of sodium ion transport in crystalline $\alpha$-Na$_2$Si$_2$O$_5$ illustrated by the limited effect of temperature on the $^{23}$Na line widths and spin lattice relaxation rates $T_{1(\rho)}^{-1}$. These observations are key findings which explain the large difference in the Na$^+$ ion conductivities and activation
energies reported for Sr$_{0.55}$Na$_{0.45}$SiO$_{2.775}$ and are due to large difference in sample composition (presence and/or absence of Na$_2$O 2SiO$_2$ glass and crystalline $\alpha$-Na$_2$Si$_2$O$_5$) and thermal history of the sample.

The experimental work presented here addresses the existing debate regarding the nature of the charge carrier in sodium strontium silicates by confirming the existence of fast sodium transport in an amorphous glassy Na$_2$O 2SiO$_2$ component of the sample. These results highlight some potential materials issues with alkali metal substitution strategies for high temperature inorganic solid state electrolytes. However, we hope it will also highlight further the potential for using non crystalline solids as fast ionic transport.$^{68}$
